

Using Individual-Level Randomized Treatment to Learn about Market Structure[†]

By LORENZO CASABURI AND TRISTAN REED*

Interference across competing firms in RCTs can be informative about market structure. An experiment that subsidizes a random subset of traders who buy cocoa from farmers in Sierra Leone illustrates this idea. Interpreting treatment-control differences in prices and quantities purchased from farmers through a model of Cournot competition reveals differentiation between traders is low. Combining this result with quasi-experimental variation in world prices shows that the number of traders competing is 50 percent higher than the number operating in a village. Own-price and cross-price supply elasticities are high. Farmers face a competitive market in this first stage of the value chain. (JEL L13, L14, O13, Q12, Q13)

A common challenge in experimental research is interference across treatment units, when the treatment status of an individual affects the outcomes of others. For example, a treatment that subsidizes some firms may change prices and quantities of other firms in the same market. In this case, the average differences between treatment and control firms in these outcomes cannot be interpreted as average treatment effects. To deal with this issue, researchers have typically employed *market-level* randomized treatments, assuming that the stable unit treatment value assumption (SUTVA) holds across markets rather than individuals. This approach however requires one to delineate market boundaries that are sufficiently large to incorporate all competitive spillovers and that enough markets are available to

achieve statistical power (Muralidharan and Niehaus 2017). In practice it is often infeasible for logistic or budgetary reasons.

In this article, we show that differences in treatment and control prices stemming from *individual-level* randomized treatment can nonetheless be used to estimate key parameters of the industry equilibrium, namely differentiation among firms, supply (or demand) slope, and own-price and cross-price elasticities. The parameters are crucial for measuring market power and analyzing counterfactual equilibria, as in the industrial organization literature (see, e.g., Berry, Gaynor, and Scott Morton 2019).

We apply this approach to study competition among buyers in an agricultural export value chain. In the field experiment, we randomly subsidize a subset of traders buying raw cocoa (cacao) from farmers in Sierra Leone. The experiment induces variation in the traders' marginal revenue: a random sample of traders are paid a per-unit bonus for delivering high-quality cocoa to five major wholesalers operating in the cocoa-producing region of Sierra Leone. The bonus is equal to approximately 5 percent of wholesale price that traders receive.

We interpret the experiment through the lens of a standard model of Cournot competition among traders. Subsidizing a random subset of traders in the same market affects prices paid to farmers and quantities purchased by both treatment and control traders. Closed-form solutions show that the average difference in prices paid by treatment and control traders recovers the degree of differentiation among traders, which summarizes a trader's ability to buy while paying farmers a lower price than competitors.¹ Differentiation of buyers from the perspective of the seller could stem from a variety of factors such as reliability of demand, timeliness of payment, the buyers' ability to provide credit, search costs, or other idiosyncratic aspects of the relationship such as friendship or trust. Intuitively, when traders are undifferentiated from the farmer's perspective, the law of one price must hold. Additionally, the treatment-control difference in quantities identifies the slope of the trader inverse supply curve.

In the experiment, treatment and control traders pay similar prices. However, subsidized traders are 80 percent more likely to provide advance payments (27 percent versus 15 percent), suggesting that estimates of trader differentiation may vary once accounting for non-price competition. To account for it, we combine these results into an average treatment and control difference in the *effective price*, which describes the net present value of all payments to the farmer. To compute the effective price we follow several strategies, relying on cross-sectional variation in price and advances (our baseline strategy), heterogeneity in treatment responses along these two margins, rural banks' interest rates, and an auxiliary experiment to measure farmers' time preferences. In our baseline specification, treated traders pay an effective price higher than control traders by about 8.5 percent of the subsidy value, and results are qualitatively similar across different methods. In addition, treatment traders, who represent about 20 percent of the traders in the markets, purchase more than four times as much cocoa as control traders.

¹Formally, the differentiation is defined as 1 minus the ratio between the slopes of a trader's inverse supply to own quantity and to each competitor's quantity.

Due to competitive spillovers, one cannot interpret these average treatment and control differences as average treatment effects. Nevertheless, randomization is still essential to interpret the results through the lens of the model, as it ensures subsidies are uncorrelated with trader characteristics and thus that the treatment-control price differences arise only because of the subsidy and not underlying differences in cost. Our preferred estimate suggests that overall traders are relatively homogeneous, with a low value of the differentiation parameter, 0.09 on a 0–1 scale with 90 percent confidence interval of $[-0.11, 0.47]$. The slope of the inverse supply curve is identified by combining the estimated differentiation parameter with treatment-control differences in quantities, and has a value of 0.35 $[0.24, 0.48]$. These results are quite robust to alternative approaches to compute the effective price, with the highest differentiation rate (0.22) found when using data from the auxiliary experiment that measures farmers' required rate of return.

By combining these parameters with the number of firms competing for farmers' supply, one can compute own-price and cross-price supply elasticities and undertake counterfactual analysis. However, the number of firms in the market may not be directly observed. In our setting, traders are highly mobile across space and so is not clear how many bid for a given farmer's output. Nonetheless, it is possible to infer the effective number of firms in the market by combining the experimental results with an estimate of the pass-through rate to farmers of a change in the wholesale price affecting all traders in the market, not just those receiving the experimental treatment. The world price is used as an instrument for the wholesale price, yielding an estimate of the pass-through that is quite high, or 0.92, in line with other studies of the regional cocoa industry, e.g., Gayi and Tsowou (2015).

The number of competitors for a given farmer's supply implied by this pass-through rate and the trader differentiation rate is 12 $[9.5, 21.2]$. This value is around 50 percent higher and significantly different (applying a 90 percent confidence interval) from the average number of traders we count operating in a village. This result suggests that markets cannot easily be delineated by village boundaries because farmers can sell their cocoa to traders outside their village. In supplementary analysis, we rule out alternative models of conduct (e.g., monopsony pricing) and we show that alternative moments from the data give similar values of differentiation and of the number of firms, providing additional support for the model.

Relatively low differentiation, high pass-through of common shocks, and large number of effective competitors suggest this market is highly competitive. Analysis of supply elasticities derived from these parameters supports this claim. The own-price supply elasticity, or the percent increase in quantity a trader experiences in response to a 1 percent increase in own price, holding constant the prices of all the other competitors, is very high, at 327 (in the limit case of perfect competition, with atomistic firms, this elasticity would be infinite). The cross-price supply elasticity is also large, at -29 : if one of the competitors increases the price by 1 percent and competitors do not respond, each of the other 11 competitors loses about one-third of its supply. The competitiveness of the market is also illustrated by an estimate of the impact of the experimental subsidy on aggregate prices and quantities, relative to a counterfactual without the experiment. The experimental subsidy induced an increase in price of 25 percent of the subsidy value for treatment traders and of

16.5 percent for control ones. Treatment traders increased supply by 174 percent and control traders reduced it by 38 percent, suggesting that the majority (90 percent) of the treatment traders' increase in quantity comes from stealing control traders' market share, rather than from an increase in aggregate supply.

The article makes progress in the literature on the implications of interference in experiments, sometimes called “spillovers” or “externalities,” which occurs when the treatment status of an individual affects the outcomes of others (Baird et al. 2018). Several recent experimental and quasi-experimental studies use market-level variation in individual-level treatment to study competition (Jensen and Miller 2018; Mitra et al. 2018; Busso and Galiani 2019; Rotemberg 2019; Bergquist and Dinerstein 2020). An implicit assumption in this strand of work is that the SUTVA required for standard experimental analysis holds when comparing markets.² Donaldson (2015) argues this assumption is unlikely to hold if markets are integrated through trade. A potential response is to work with very large randomization clusters that encompass most of the spillovers (see, e.g., Muralidharan and Niehaus 2017; Burke, Bergquist, and Miguel 2019). However, such an approach is often either very expensive or not logistically feasible because the number of such clusters is too small. Our alternative approach relies on violations of the SUTVA and individual-level randomized variation in firms' marginal revenue to estimate the parameters of a standard industry equilibrium model. While our focus is a model of supply to potentially differentiated buyers, similar arguments combined with experimental variation in marginal cost could be used to estimate a model of demand for potentially differentiated products (e.g., Vives 2001).

In addition to demonstrating how individual-level variation can be used to identify the parameters of the industry equilibrium, our analysis illustrates why randomization across geographies could be insufficient for identification of these parameters. The reason is that geographic market boundaries based on arbitrary measures of distance or administrative units need not correspond to the market that is relevant for competition. In our setting, the finding that the estimated number of traders is greater than the average number of traders in a village suggests that the market is larger than a single village. Randomization across villages therefore would not deliver market-level variation. This challenge to inference posed by arbitrary market boundary definitions has been recognized in the industrial organization literature (see, e.g., Carlton 2007; Genakos and Pagliero 2022). This article demonstrates how individual-level randomization combined with a quasi-experimental estimate of the pass-through rate can be used to infer the size of the relevant market.

Our approach has broad application in policy analysis. Weyl and Fabinger (2013) highlight the pass-through rate as an economic tool for assessing the incidence of taxes or subsidies affecting all firms in a market. An estimate of the differentiation rate allows one to study further the incidence of taxes or subsidies given to only a

²Other recent experiments (or natural experiments) featuring market-level variation include Crépon et al. (2013); Mobarak and Rosenzweig (2014); Lalive, Landais, and Zweimüller (2015); Muralidharan, Niehaus, and Sukhtankar (2016); Cunha, De Giorgi, and Jayachandran (2018); Filmer et al. (2018); Burke, Bergquist, and Miguel (2019); Hildebrandt et al. (2020); Breza and Kinnan (2021); and McKenzie and Puerto (2021). In nonexperimental studies of competition, industry equilibrium models are typically estimated using a time series of prices (and costs) and instrumental variables (Graddy 1995; Osborne 2005).

subset of firms. Many industrial and agricultural policies are implemented in this way. For example, while in West Africa governments have broadly preferred universal subsidies for fertilizer use, in East Africa subsidies are only available to poorer farmers (Druilhe and Barreiro-Hurlé 2012). Outside of agriculture, subsidies often target only small or medium-sized firms (Chatzouz et al. 2017; Rotemberg 2019), exporters (Rodrik 1995, Panagariya 2000; Kalouptsi 2018), or the politically connected (Khwaja and Mian 2005; Faccio 2006; Rijkers, Baghdadi, and Raballand 2017). Intuitively, as we demonstrate through counterfactual analysis, when subsidies are offered only to a subset of firms, the equilibrium effect of the subsidy depends both on the number of firms in the market and the extent to which they are differentiated. Identification of these parameters requires both an estimate of the market-level pass-through rate and of the average difference in prices paid by treatment and control firms.

Our estimate of buyer differentiation informs a literature on credit transactions in the context of agriculture, which are described as interlinked when credit is provided by buyers and output prices are codetermined with the interest rate (see Bardhan 1980; Bell 1988).³ We find that, in response to subsidies, treated traders use credit to farmers to secure supply. The advance payment is repaid when the farmer accepts a below market price for output at harvest time. While other studies have emphasized that credit supply is diminished in the absence of the market power required to sustain a relational credit contract (McMillan and Woodruff 1999; Macchiavello and Morjaria 2020), we demonstrate that credit provision need not coincide with high market power of credit providers. There are two plausible explanations for this finding. First, credit contract enforcement through customary legal institutions (i.e., the Paramount Chieftaincy described by Acemoglu, Reed, and Robinson 2014) may be effective, obviating the need for relational credit contracts. Second, as in the analysis of African trade credit relationships by Fisman and Raturi (2004), competition may increase borrowers' incentives to establish creditworthiness, by reducing holdup concerns on the lender side.

Finally, our results contribute to a substantial literature describing the industrial organization of agricultural markets in low- and middle-income countries. Prior studies of farm-gate buyers' market power have relied on primarily observational, rather than experimental evidence, analyzing trader price-cost margins (for sub-Saharan Africa, see, e.g., Fafchamps, Gabre-Madhin, and Minten 2005; Osborne 2005; Sitko and Jayne 2014), price dispersion across space (Fackler and Goodwin 2001; Aker 2010), or the pass-through of international prices along the supply chain (Fafchamps and Hill 2008; Dillon and Barrett 2016).⁴ To the best of our knowledge, this is the first experiment that randomized any treatment at the

³Casaburi and Willis (2018); Casaburi and Macchiavello (2019); Ghani and Reed (2022); and Macchiavello and Morjaria (2020) provide recent empirical contributions on interlinked credit transactions in agricultural value chains in sub-Saharan Africa. Emran et al. (2021) documents the importance of financing middlemen in Bangladesh edible oils supply chain. More broadly, interlinked credit is a feature of all economies in the form of trade credit, which is an important source of finance for smaller firms (Petersen and Rajan 1997), certain industries (Fisman and Love 2003), and for international trade (Antràs and Foley 2015). In the United States, non-farm enterprises with fewer than 500 employees rely on trade credit for about 60 percent of their external finance (Mach et al. 2006).

⁴Chatterjee (2020) uses price dispersion across space to study competition in crop markets in India. More broadly, recent theoretical and empirical contributions on the role of intermediaries in supply chains include Antràs

trader level in agricultural markets and that used experimental subsidies to study competition. Our finding that farm-gate buyers in Africa have more limited market power consistent with evidence in the recent review by Dillon and Dambro (2017). Bergquist and Dinerstein (2020) and Iacovone and McKenzie (2019) study experimentally how vendors (of maize and fresh produce, respectively) adjust consumer prices in response to market-level subsidies affecting marginal costs. In these retail settings (distinct from the farm-gate), these authors find a high degree of market power.

I. A Simple Model of Strategic Competition between Treatment and Control Firms

This section presents the model of imperfect competition we use to interpret our experimental results. The model illustrates how a subsidy (treatment) to a randomly-selected subset of firms in the market affects prices and quantities of all firms, not just the treated ones. In other words, the SUTVA fails. Given our empirical setting, we focus on demand-side (i.e., trader) oligopsonistic competition, though a similar approach could be used to estimate a model with supply-side oligopolistic competition. The model is stylized and makes important assumptions, e.g., about conduct and functional forms. Since we use our empirical results to validate these assumptions, we postpone to Section IV a detailed discussion of these assumptions and their implications.

The model provides a transparent closed-form mapping between individual-level treatments and three parameters describing the industry equilibrium. First, the average difference in prices paid to farmers by treatment and control traders identifies the degree of differentiation among traders. This parameter is defined as 1 minus the ratio between the slopes of a trader's inverse supply to own quantity and to each competitor's quantity. It thus measures the extent to which each trader is "insulated" from its competitors. Intuitively, without differentiation, the law of one price must hold and there is no difference in price paid by treatment and control traders.⁵

Second, for given differentiation, the average difference in quantities between treatment and control traders identifies the slope of the inverse supply curve facing the trader.

Third, for given differentiation and slope of inverse supply, the market-level pass-through rate (i.e., the response of the farmer price to a change in the wholesale price common to all traders) identifies the number of firms effectively competing in the market. Counting the number of firms in a market requires delineating market boundaries. This exercise can be contentious, for instance in anti-trust litigation (see, e.g., Carlton 2007). For this reason, it is important to estimate the number of firms rather than taking it as given within geographic or temporal boundaries.

and Costinot (2011); Bardhan, Mookherjee, and Tsumagari (2013); Chau, Goto, and Kanbur (2016); Maitra et al. (2017); and Emran et al. (2021).

⁵To be clear, the buyer differentiation we discuss is distinct from differentiation of products across sellers.

A. Preliminaries

Producers.—In the market, there are measure one homogeneous producers, each producing a unit of output and there are n buyers who compete for these producers' output, the monopsony case being $n = 1$. The inverse supply buyer i faces is⁶

$$(1) \quad p_i = \alpha + \beta q_i + \gamma \sum_{j \neq i} q_j.$$

This equation adapts the standard model of linear demand and differentiated producers (see, e.g., Vives 2001) to a setting that features imperfect competition among buyers rather than sellers.

From the producers' perspective, buyers are differentiated at rate $\Gamma \equiv 1 - \frac{\gamma}{\beta}$. If $\Gamma = 0$, buyers are homogeneous: the slope of the inverse supply to own quantity equals the slope to a competitor's quantity. If $\Gamma = 1$, buyers are local monopolists: a buyer's inverse supply does not depend on other buyers' quantities.

Buyers.—The profit of buyer i is given by

$$(2) \quad \pi_i = q_i(v_i - p_i),$$

where q_i is the quantity purchased, v_i is the wholesale price net of costs, and p_i is the (effective) price the buyer pays to producers.

Assume buyers are ex ante symmetric in the resale price v . The experiment introduces a subsidy, s , for a share μ of the buyers, who then have a higher resale price. Therefore, $v_i = v + s$ for treatment buyers and $v_i = v$ for control buyers. Below we refer to variables for treatment (control) buyers with subscript T (C).

B. Industry Equilibrium

Assume conduct takes the form of Nash-in-quantities competition, in which each buyer sets q_i strategically, taking into account competitors' choices q_{-i} and market structure n . This equilibrium concept includes Cournot oligopsony and monopsony for $n = 1$.

⁶This inverse supply can be microfounded by assuming a representative producer whose cost function features love for variety. Specifically, the producer profit function is: $V(p_1, \dots, p_n, q_1, \dots, q_n) = q_0 + \sum_{i=1}^n p_i q_i - C(q_1, \dots, q_n) = q_0 + \sum_{i=1}^n p_i q_i - (\alpha \sum_{i=1}^n q_i + \frac{1}{2} \beta \sum_{i=1}^n q_i^2 + \gamma \sum_{j \neq i} q_i q_j)$, where q_0 is the output that is not sold to buyers (e.g., consumed, not harvested), p_i is the price paid by buyer i and q_i is the output sold to buyer i (the solution presented in this section assumes $q_0 > 0$). A representative agent strategy featuring love for variety may itself be considered a "reduced-form" approach that aggregates heterogeneous producers having idiosyncratic preferences for each buyer.

Consider a group-symmetric equilibrium in which firms in the same treatment group behave similarly. The first-order conditions associated with each group's profit maximization are

$$(3) \quad q_T = \frac{(2\beta - \gamma)(v - \alpha) + s(2\beta + \gamma(n - 1)) - s\gamma\mu n}{(2\beta - \gamma)(2\beta + \gamma(n - 1))};$$

$$q_C = \frac{(2\beta - \gamma)(v - \alpha) - s\gamma\mu n}{(2\beta - \gamma)(2\beta + \gamma(n - 1))}.$$

By the inverse supply functions in equation (1), equilibrium prices are

$$(4) \quad p_T = \frac{\alpha\beta(2\beta - \gamma) + v(2\beta - \gamma)(\beta + \gamma(n - 1)) + \beta\gamma\mu ns + s(\beta - \gamma)(2\beta + \gamma(n - 1))}{(2\beta - \gamma)(2\beta + \gamma(n - 1))};$$

$$p_C = \frac{(2\beta - \gamma)(\beta(\alpha + v) + \gamma v(n - 1)) + \beta\gamma\mu ns}{(2\beta - \gamma)(2\beta + \gamma(n - 1))}.$$

These prices imply variable markdowns, p_i/v_i . Treatment (control) quantities are increasing (decreasing) in the subsidy amount s and both are decreasing in the share of treated buyers μ . Both control and treatment prices are increasing in both s and μ . These intuitive comparative statics show how treatment changes the behavior of control firms, as well as treatment ones.

C. Empirical Identification of the Market Structure Parameters

We now review the equilibrium equations that identify the two parameters of the supply curve, Γ and β , and the effective number of firms, n .

Average Treatment-Control Differences in Quantities and Prices.—For a given subsidy level, s , the differentiation parameter Γ and the slope of the supply curve β are identified by the treatment and control differences in prices and quantities

$$(5) \quad \Delta p \equiv p_T - p_C = \frac{s(\gamma - \beta)}{\gamma - 2\beta} = \frac{s\Gamma}{1 + \Gamma};$$

$$(6) \quad \Delta q \equiv q_T - q_C = \frac{s}{2\beta - \gamma} = \frac{s}{\beta(1 + \Gamma)}.$$

Intuitively, Δp is increasing in Γ . If traders are homogeneous (i.e., $\Gamma = 0$), there can be only one price in the market; with higher differentiation, different prices can coexist and control traders can pay producers a price lower than do treated traders. Conversely, Δq is instead decreasing in Γ : if traders are more differentiated, market stealing from control to treatment will be smaller. Intuitively, Δq is also decreasing

in β the slope of the inverse supply curve. These results do not depend on n or the share of treatment traders μ .

From the estimates of $\Gamma = 1 - \frac{\gamma}{\beta}$ and β , we can obtain the own-price price elasticity, η_{ii} , and the cross-price elasticities, η_{ij} :

$$(7) \quad \eta_{ii} \equiv \frac{\partial q_i p_i}{\partial p_i q_i} = \frac{\beta + \gamma(n - 2)}{(\beta + \gamma(n - 1))(\beta - \gamma)} \frac{p_i}{q_i},$$

$$(8) \quad \eta_{ji} \equiv \frac{\partial q_j p_i}{\partial p_i q_j} = -\frac{\gamma}{(\beta + \gamma(n - 1))(\beta - \gamma)} \frac{p_i}{q_j}.$$

These results demonstrate how average individual-level treatment and control differences from a randomized experiment can be used to measure the extent to which individuals in a market are differentiated, and how this information can be used to back out the supply elasticity. These elasticities shape the quantity responses to price changes (including to changes induced by the subsidy) for a given number of competitors.

One approach to recover these elasticities would be to define the number of buyers n as the ones that are counted operating in some geographic area, such as a village. However, to do so would be arbitrary, as the village is not obviously the relevant market for competition. In our context at least, buyers are highly mobile across villages on motorbikes, and so it is implausible that villages are independent markets. Therefore, we use additional information from the data to estimate the number of buyers, rather than to take it as given.

Pass-Through of the Wholesale Price.—The model provides a method to estimate n without the need to delineate market boundaries. For a given estimate of Γ , n is identified by the pass-through rate, which describes how producer prices p_i respond to a change in v , the component wholesale price that is common to all buyers. The pass-through rate is given by

$$(9) \quad \rho \equiv \frac{\partial p_C}{\partial v} = \frac{\partial p_T}{\partial v} = 1 - \frac{1}{1 + \Gamma + n(1 - \Gamma)},$$

which is decreasing in Γ and increasing in n . In practice, Γ and n are estimated jointly, not sequentially.

II. Experimental Subsidies to Farm-Gate Buyers in the Sierra Leone Cocoa Industry

Setting.—Cocoa is an important crop for Sierra Leone, where it is the largest agricultural export by value, comprising 8.6 percent of exports in 2017 according to the United Nations (2020). Approximately 75 percent of global supply of cocoa originates from West Africa (ICCO 2019).

A brief schematic of the industry follows. Wholesalers are based in three main towns along the Moa river plain in Eastern Province, as shown in Figure 1. They source cocoa from a network of traders (intermediaries) with whom they typically

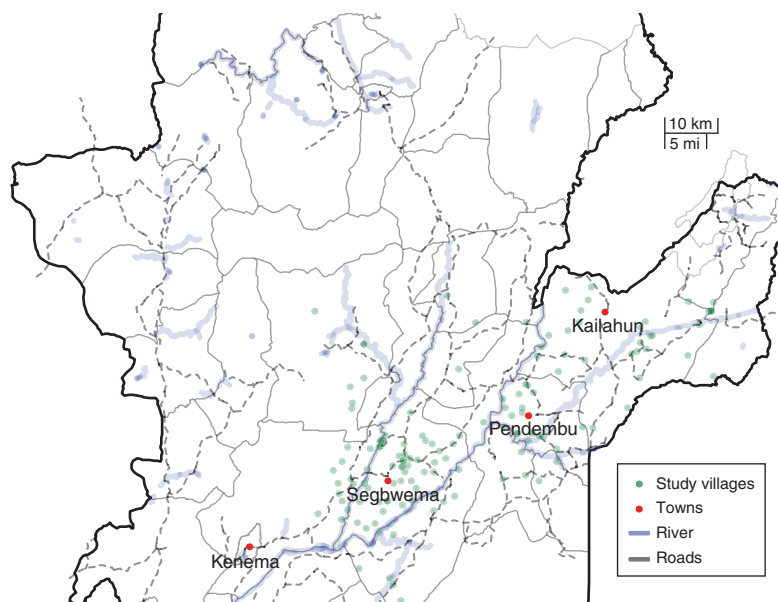

FIGURE 1. MAP OF STUDY VILLAGES

have exclusive relations such that a trader almost always delivers cocoa only to a single wholesaler. Traders purchase cocoa from farmers in villages near the towns and deliver to wholesalers, who sell onwards to exporters in the provincial capital of Kenema or the national capital Freetown. Though Sierra Leone supplies only 0.77 percent of global cocoa exports, the structure of the country's industry is similar to other exporters in West Africa, though in Sierra Leone there is no government involvement in downstream purchases.

The provision of loans by traders to farmers is an important feature of this industry, suggesting the hypothesis that traders are potentially differentiated, lending them market power. Loans are typically given in the form of advance payment, when traders pay for cocoa in advance of delivery. Farmers use the advance payments for production or for consumption smoothing. Production mainly involves hiring workers to harvest the cocoa from the trees, which are planted infrequently. Farmers then pay interest on these advances by selling at a below market price for subsequent sales. Verbal contracts define the amount to be deducted from the final payment. Contracts may be enforced by customary legal institutions (see, e.g., Acemoglu, Reed, and Robinson 2014 and Sandefur and Siddiqi 2013), or through relational contracts, in which the farmers' fear of disrupting future business with the trader could be sufficient to avoid default (see, e.g., Fafchamps 2003; Macchiavello and Morjaria 2015; Blouin and Macchiavello 2019).

SUTVA and Experimental Analysis within a Competitive Market.—In this setting, competitive forces may cause a violation of the stable unit treatment value assumption (SUTVA) required for standard experimental analysis. Average differences in outcomes between treatment and control groups therefore cannot be interpreted as treatment effects in the potential outcomes framework of Rubin (1974).

In our setting, the SUTVA violation is plausible because treatment and control traders operate in the same village. If a village's supply of cocoa is not perfectly elastic, the offer of a higher price by treatment traders would induce a strategic response from control traders. The SUTVA could also be violated if randomization is conducted at the village level, for instance if the experiment offered the subsidy to all traders in certain treatment villages, while offering it to none in control villages. Each trader operates in 4.6 villages on average, with significant multimarket contact between traders. Traders' mobility (on motorcycles) and the relatively small geographic region of the cocoa-producing area imply that, for a given trader, most markets are contestable. This becomes clear inspecting Figure 1, which shows the locations of the three towns Segbwema, Pendembu, and Kailahun where the five wholesalers operate, as well as the study villages from which study traders procure cocoa. All three towns and villages lie within 40 miles of each other.

While experimental studies in development economics often assume the SUTVA holds across villages, this assumption may be controversial, if not implausible. The model in Section I establishes a method to overcome this challenge. It provides a means to interpret the average differences between treatment and control prices and quantities when SUTVA does not hold. Further, it demonstrates how combining these differences with an estimate of the pass-through rate identifies the number of firms competing in the market.

Experiment Design and Implementation.—As with many export products, a key policy concern in the cocoa industry is how to upgrade average quality. The transmission of a quality price premium to farmers is a necessary condition to do this in a decentralized manner. Our experiment sought to demonstrate how changes in traders' marginal revenue for high quality cocoa translates into price signals received by cocoa farmers. We developed the experiment in partnership with five private wholesalers.⁷ Ultimately, the experimental sample comprised 80 traders—henceforth, study traders.

When studying prices, it is important to focus on narrowly defined homogeneous goods, lest price differences reflect differences in quality. The quality of cocoa is heterogeneous, and market prices depend on a variety of characteristics including moisture content, mold, germination, lack of fermentation and a discoloration known as slate. Though there is no official standard of quality in the market, wholesalers and traders agree on broad determinants of quality that are consistent with international standards (see Fold 2005). To implement the experiment, we developed with wholesalers a quality index that correlates well with baseline prices, described in further detail in online Appendix Section A. When traders arrive at the warehouse, inspectors hired by the research team sampled 50 beans from each bag, and scored each bean to create an index of quality—grades A, B, or C—that was applied to each bag. Formal grading was explained to traders as an initiative to make wholesaler pricing, which was already based to some extent on inspection of quality, more

⁷This experiment was registered in the AEA RCT Registry (see Casaburi and Reed 2022.)

rigorous. The analysis in this article focuses on grade A cocoa, the grade targeted by the experimental subsidy, unless otherwise specified.

The experiment was implemented as follows. From mid-October to the end of December 2011, roughly the end of the harvest season, a randomly-selected subset of 40 traders we offered a bonus of 150 leones per pound of cocoa sold—5.6 percent of the average wholesale price—when selling good quality (grade A) cocoa to the wholesalers. At the beginning of the experiment, traders were informed the bonus was because of increased demand for high-quality cocoa. Randomization of the bonus treatment occurred at the individual trader level. We implement a pairwise randomization strategy (Bruhn and McKenzie 2009), which matches traders within wholesalers according to their self-reported estimate of the volume of purchases since the beginning of the cocoa season and then assigned treatment and control within pairs. Of the 84 traders identified by wholesalers, four were outliers with respect to baseline quantity relative to other traders within the same wholesaler, and could not be matched to other traders in our randomization strategy. Thus, the final sample selected for randomization was 80 traders.

A. Data and Summary Statistics

Over the course of the experiment, we collected a variety of original data from cocoa traders using three instruments: (i) a trader baseline survey, which recorded basic information on the trader and his business (all are male); (ii) a transaction survey, which for each transaction recorded the unit value paid to the farmer, the shipment weight in kilograms, and cocoa quality according to the grading scheme; and (iii) a farmer listing, administered at baseline and then in two follow-up rounds, in which traders were asked to list the farmers they buy from, and whether they had provided them with advance payment (in the last 12 months at baseline and in the last month in the two follow-ups).⁸ Online Appendix Section F.1 shows a time line of the harvest season, indicating the times at which each instrument was deployed. Transaction data collection ran from September 24, 2011 to December 31, 2011 and the cocoa transaction survey was administered continuously over this period. We began paying bonuses to treatment traders on October 15, 2011 until December 31, 2011. The exact dates each trader responded to the transaction survey varies, given that they arrived at the wholesalers' warehouses at different times. Data collection was suspended for approximately two-and-a-half weeks between late November and early December because of project budget constraints due to a higher volume of recorded transactions than we had initially budgeted. We cannot be certain how this unexpected break in ability to pay affected trust in the subsidy, but we do observe that treatment traders continued to bring more quantity than control traders after the subsidy was reintroduced. The farmer listings were given to traders the first time they arrived in October, December, and January.

⁸Replication data and codes are available on the Inter-University Consortium for Political and Social Research (Casaburi and Reed 2022).

TABLE 1—BASELINE TRADER SUMMARY STATISTICS

Covariate	Treatment	Control	Treatment – control
<i>Panel A. Baseline interview</i>			
Self-estimate bags sold in 2011	20.0 (28.3)	18.6 (18.5)	1.5 (2.23)
Age, years	38.2 (8.2)	36.9 (10.2)	1.4 (1.91)
Years trading cocoa	8.1 (5.4)	8.9 (5.5)	–0.8 (1.2)
Years selling to study wholesaler	5.7 (4.8)	7.3 (4.9)	–1.6 (0.86)
Cement or tile floor in house $\in \{0, 1\}$	0.53 (0.51)	0.63 (0.49)	–0.1 (0.1)
Mobile phone owner $\in \{0, 1\}$	0.90 (0.30)	0.93 (0.27)	–0.03 (0.06)
Access to storage facility $\in \{0, 1\}$	0.88 (0.33)	0.78 (0.42)	0.10 (0.09)
Villages operating in	4.25 (1.64)	4.87 (2.02)	–0.62 (0.39)
Number of suppliers per village	5.8 (3.3)	6.2 (3.6)	–0.35 (0.84)
Share of suppliers given credit since March	0.72 (0.32)	0.68 (0.28)	0.04 (0.05)
<i>Panel B. Pretreatment shipment data</i>			
Price paid to farmer (shipment-level)	3,137 (154)	3,136 (151)	1.2 (41.9)
Pounds sold during pretreatment (weekly)	89 (235)	151 (583)	–62 (41)

Notes: Panel A presents balancing for the variables defined in the baseline survey. Some baseline survey variables are missing for one trader. The column “Treatment – control” presents results from a regression on treatment and randomization pairs. Panel B presents balancing for variables from pre-experiment shipment data. Prices are defined only for the subset of traders that delivers at least one shipment during this period. Quantities are defined for all traders and are equal to zero for traders who do not make any delivery in the pre-experimental period. Standard errors are clustered by trader.

Our key outcome variables are the transaction price, measured as the unit value of each shipment, and a dummy for whether the trader had provided an advance payment to a farmer in the previous month, in either the second or third round of the farmer listing. The cocoa transaction survey was administered as follows. During the experiment, when traders arrived at the warehouse, inspectors from the research team measured quantity and quality of their shipment. Enumerators then asked traders the price per pound they paid to farmers and the name of the village where the cocoa mostly originated. Traders often mix cocoa from different farmers in the same bag, and so farmer prices reported are the average per unit purchase price paid by a trader for the cocoa in the bag.

Panel A of Table 1 presents summary statistics from the trader baseline survey and the first trader listing. Treatment and control groups are balanced on these trader-level covariates. In the baseline listing, traders report purchasing cocoa from 123 villages. The average trader operates in 4.6 villages, and buys from 6 farmers per village. On average, based on the trader survey, there are 7.8 traders operating

in a village. However, only 3.2 of these are study traders, suggesting that about 60 percent of the traders in the market are non-study traders (i.e., working with other wholesalers). Study traders report having given at least one loan to about 70 percent of the suppliers listed at baseline in the previous year.

Attrition.—In the three weeks preceding the intervention, 60 of the 80 traders included in the study visited the warehouses (29 control and 31 treatment). Panel B of Table 1 reports balance for prices and quantities in the three weeks before the intervention, and shows there is a marginally significant difference in quantities ($p = 0.136$). During the experiment, 75 traders visited the warehouse (37 controls and 38 treatment). We include in all regressions randomization pair fixed effects and thus we effectively drop pairs including those traders that did not visit the warehouses.

III. Experimental and Quasi-Experimental Results

In this section we report the average differences between treatment and control traders in prices paid to farmers, provision of advance payments, and quantities of cocoa purchased, and the quasi-experimental results on pass-through.

A. Average Treatment and Control Differences

Farmer Prices.—First, we examine treatment and control differences in prices (i.e., unit values) that traders pay to farmers. Enumerators asked traders the unit value for each shipment, which dividing by weight yields a measure of price. If the trader made payments at different times (e.g., before and after harvesting), enumerators recorded the total price paid to the farmer, including anything paid before harvest. We denote this price with \tilde{p} , so to differentiate it from the effective price, p , which accounts for the farmer's valuation of advance payment and is defined formally in Section IVA.

Figure 2 displays the price results graphically. It shows weekly averages for (i) world prices,⁹ (ii) wholesaler prices, (iii) prices treatment traders paid to farmers, and (iv) prices control traders paid to farmers. The vertical red line marks the inception of the experimental treatment. There are two observations to make. First, farmer prices follow closely wholesaler prices, which move with world prices. In particular, domestic prices respond to the sharp decrease in the world price that occurred in November 2011. Second, there is no obvious gap between the average prices that treatment and control traders pay to the farmers, either before or after the treatment begins. Suggestive evidence in line with the hypothesis that the SUTVA is violated comes from the fact that the treatment-control price gap is larger in the first weeks of the experiment (i.e., in the first three weeks of the experiment, the treatment

⁹Specifically, we report the front month price on the Intercontinental Exchange for the physical delivery of 10MT of exchange-grade cocoa from a variety of African, Asian and Central and South American origins to any of five US delivery ports, with trading code NYCC. We convert prices from US\$/metric ton to Leones/pound using the prevailing exchange rate of US\$1 = 4,400 Leones.

FIGURE 2. COCOA PRICES

Notes: The figure presents average weekly prices for (i) international cocoa prices; (ii) prices the study wholesalers pay to the traders; (iii) prices control traders pay to farmers; (iv) prices treatment traders pay to farmers. All prices are in leones (1,000s) per pound. Wholesale and farmer price data collection was suspended for most of three weeks (w47–w49). The vertical line marks the beginning of the intervention period.

coefficient is 31, $p = 0.09$), and then decreases as control traders respond to higher prices offered by treatment traders.

We estimate the average treatment and control difference in prices using the following regression, where an observation is a shipment s delivered by trader i of randomization pair z in week t :

$$(10) \quad \tilde{p}_{sit} = \eta_{z(i)} + \eta_t + \beta_{\tilde{p}} \text{Treat}_i + \epsilon_{sit},$$

where $\eta_{z(i)}$ and η_t are randomization pair and week fixed effects, respectively. We cluster standard errors at the unit of treatment (i.e., the trader). Results are similar when allowing for double clustering by trader and village (Cameron, Gelbach, and Miller 2011).

The term $\beta_{\tilde{p}}$ is the coefficient of interest. Column 1 of Table 2 presents the regression without week fixed effects, and $\hat{\beta}_{\tilde{p}} = -32.5$ (s.e. = 48.4). Column 2 includes week fixed effects and yields $\hat{\beta}_{\tilde{p}} = -5.5$ (s.e. = 15.4). While the two coefficient estimates are not statistically distinguishable from each other or from zero, the coefficient is greater in absolute value without week effects, suggesting that selection in when to sell matters. It appears that the experiment induced treatment traders to stay longer in the market at the end of the season, when prices were lower.

The treatment may also have induced selection into which traders make purchases and the locations traders visit. To account for that possibility, columns 3 to 5 include controls referring alternatively to the trader, the village where the majority of cocoa in the shipment originated,¹⁰ and both. See the notes to Table 2 for complete list of

¹⁰Eighty of the 123 villages listed at baseline appear as “main village” in at least one shipment, covering approximately 85 percent of the suppliers listed at baseline.

TABLE 2—TREATMENT – CONTROL DIFFERENCES IN PRICES

	(1)	(2)	(3)	(4)	(5)
Treatment trader	−32.52 (48.40)	−5.47 (15.39)	−5.92 (17.58)	−13.15 (13.63)	−6.32 (15.79)
Control group mean	2,987	2,987	2,987	2,987	2,987
Week fixed effects		X	X	X	X
Trader controls			X		X
Village controls				X	X
Observations	1,079	1,079	1,060	1,079	1,060

Notes: The table reports the difference between the prices paid by treatment and control traders to farmers during the experiment, measured in leones per pound. The subsidy to treatment traders was Le. 150 per pound. An observation is a shipment delivered by the trader to a wholesaler. Trader controls are baseline values of pounds of cocoa sold, number of villages operating in, number of suppliers buying from, share of clients given credit in baseline, age, years of working with wholesaler, and dummies for ownership of a cement or tile floor, mobile phone, and access to a storage facility. Village controls are baseline share of suppliers begin given credit, number of other bonus traders and number of study traders, miles to nearest town, and number of clients across all traders. Data on some trader controls are missing for one trader and thus the number of observations falls in columns 3 and 5. Standard errors are clustered at the level of the trader.

these controls. The coefficient $\hat{\beta}_p$ is quite stable across these columns, suggesting that the selection described above does not drive the results. Overall, across alternative specifications average prices paid to farmers are not different between treatment and control traders.

In online Appendix Table F.1, we also test for effects on prices of B and C grade cocoa, which were not subsidized. We find a statistically significant difference for grade B prices, however the value is still far from the value of the subsidy. Field interviews suggest that treatment traders were somewhat more willing to pay the grade A price for cocoa that had some probability of being grade A.

Advance Payments.—Second, we estimate average treatment-control differences in the provision of advance payments during the intervention period, using the following linear probability model,

$$(11) \quad \text{AdvancePayment}_{fi} = \eta_{z(i)} + \beta_a \text{Treat}_i + \nu_{fi}.$$

An observation is a farmer listed as a regular supplier in the trader baseline survey. $\text{AdvancePayment}_{fi}$ is an indicator of whether trader i reported paying farmer f an advance payment during the course of the experiment, in either of the two follow-up listing exercises.¹¹

¹¹In the listing we recorded data only on regular suppliers, and it is not clear in which direction this selection may bias our estimates of the advance payment treatment-control difference: traders may be less likely to extend advances to irregular suppliers or, on the contrary, they may be using advances particularly to attract irregular suppliers. However, in the price regressions just reviewed, which include purchases for all suppliers, not just regular suppliers, average differences between treatment and control did not vary when controlling for the number of regular suppliers in the village. This provides some assurance that traders did not contract with regular suppliers differently from how they passed value to other farmers.

TABLE 3—TREATMENT — CONTROL DIFFERENCES IN ADVANCE PAYMENTS

	(1)	(2)	(3)	(4)
Treatment trader	0.12 (0.03)	0.12 (0.03)	0.12 (0.03)	0.12 (0.03)
Control group mean	0.15	0.15	0.15	0.15
Trader controls		X		X
Village controls			X	X
Observations	1,818	1,806	1,818	1,806

Notes: The table reports the difference between treatment and control in the share of regular suppliers that receive advance payments (binary indicator) during the experimental period. An observation is a farmer a trader listed as regular supplier in the baseline survey. Trader controls are baseline values of pounds of cocoa sold, number of villages operating in, number of suppliers buying from, share of clients given credit in baseline, age, years of working with wholesaler, and dummies for ownership of a cement or tile floor, mobile phone, and access to a storage facility. Village controls are baseline share of suppliers receiving credit, number of other bonus traders and number of study traders, miles to nearest town, and number of clients across all traders. Data on some trader controls are missing for one trader and thus the number of observations falls in columns 2 and 4. Standard errors are clustered at the level of the trader.

Table 3 presents estimates of the coefficient of interest, β_a . Column 1 presents the results of estimating equation (11), which yields $\beta_a = 0.12$ (s.e. = 0.03), implying farmers reported by treatment traders in the baseline listing are 12 percentage points more likely to receive credit from these traders during the experimental period, relative to a control mean of 15 percent. In columns 2 to 4, the coefficient does not change when adding trader controls, village controls, and both set of controls together.

Note that this advance provision may cover sales of cocoa for various grades, not just grade A. In Section IVA, where we value advanced payments, we consider the implications of this issue.

Quantities.—Third, we estimate average treatment-control differences in quantity purchased from farmers. Figure 3 shows the weekly amount purchased by the study traders together and then by treatment and control groups separately. Several patterns emerge. First, purchases of treatment and control are balanced in the two weeks before the intervention, while control quantities are higher three weeks before the beginning of the intervention. Second, throughout the intervention, treatment traders purchase substantially higher volumes than control ones. Third, total quantity purchased by study traders continues to increase after the beginning of the experiment. This observation is consistent with the idea that treatment traders gained market shares at the expense of non-study traders, as well as control traders. Fourth, toward the end of the experiment, there is a stark reduction in total quantities purchased, consistent with the season ending at that time.

These results are quantified more precisely using the regression model

$$(12) \quad q_{it} = \eta_{z(i)} + \eta_t + \beta_q \text{Treat}_i + \zeta_{it},$$

where an observation captures the total purchases of cocoa trader i in week t (including zeros). Table 4 presents estimates of the coefficient of interest, β_q . Column 1 presents

FIGURE 3. PURCHASES OF COCOA

Notes: The figure shows the total amount of cocoa purchases by study traders (i.e., control and treatment traders), control traders, and treatment traders. The vertical line marks the beginning of the intervention period. Data collection was suspended for most of three weeks (w47–w49).

TABLE 4—TREATMENT – CONTROL DIFFERENCES IN QUANTITIES

	(1)	(2)
Treatment trader	398.38 (38.0)	395.57 (38.3)
Control group mean	114.6	114.6
Trader controls		X
Observations	640	632

Notes: The table reports the difference between the quantities of cocoa purchased by treatment and control traders during the experimental period. An observation is a week × trader (8 × 80). Trader controls are baseline values of pounds of cocoa sold, number of villages operating in, number of suppliers buying from, share of suppliers receiving credit from the trader at baseline, age, years of working with wholesaler, and dummies for ownership of a cement or tile floor, mobile phone, and access to a storage facility. Data on some trader controls are missing for one trader and thus the number of observations falls in column 2. Standard errors are clustered at the level of the trader.

the results of estimating equation (12), which yields $\beta_q = 398.4$ (s.e. = 38.0), indicating that during the experiment treatment traders on average purchase 398 pounds per week more than control traders, or 349 percent more than the control mean.¹² The results are robust when including trader controls in column 2. Overall, this is a large impact of the treatment.

¹²Consistent with the large difference in quantities purchased, treatment traders were more than three times as likely to visit the warehouse during the experimental period than control ones. Throughout the experiment we did not receive any complaint from either wholesalers or traders suggesting that control traders were switching to different wholesalers. This is consistent with the fact that the experiment did not change the wholesaler price for control traders.

TABLE 5—PASS-THROUGH FROM WHOLESALER TO TRADER PRICES

	(1)	(2)	(3)
Wholesaler price	0.92 (0.01)	0.91 (0.05)	0.85 (0.03)
Control group mean	3,007	3,007	2,960
Kleibergen-Paap first-stage F-stat	1,623.0	94.5	32.5
Trader fixed effects	X	X	
Village fixed effects		X	
Observations	1,254	1,254	72

Notes: The table reports the pass-through from wholesaler prices to farmer prices. Both are measured in leones per pound. In all columns wholesaler prices are instrumented with the front-month prices for liquid cocoa futures, obtained by the Intercontinental Exchange. In columns 1–2 an observation is a shipment delivered by the trader to a wholesaler before or during the intervention and standard errors are clustered by trader and date. In column 3, we collapse data in a time-series of average prices for each date and use heteroskedasticity and autocorrelation consistent (HAC) standard errors, with Newey-West kernels.

B. *Quasi-Experimental Results: Pass-Through of the Wholesale Price*

In this section, we estimate the pass-through rate to farmers of a common change in the wholesaler price (i.e., ρ , as defined in equation (9)). Estimation of ρ is complicated by the possibility of reverse causality, wherein local shocks to farmer costs and supply may affect farmer prices, which in turn affect wholesaler prices. To address this concern, we instrument wholesaler prices with the international price of cocoa, as reported by the Intercontinental Exchange. Given that Sierra Leone has a small share of the global production, it is plausible that changes in international prices are exogenous to supply conditions in Sierra Leone. Local prices are also highly correlated with international prices in the time series. Recall Figure 2, discussed in Section IVA, which showed a stark reduction in prices paid to farmers (around 22 percent) in the final month of the experiment, following a reduction in wholesaler prices, and a decline in the world price.

Table 5 presents the results on pass-through from wholesale prices to farmer prices in a regression framework. In column 1, we report estimates from two-stage least squares estimation, controlling for trader fixed effects and clustering by trader and date. The instrument has a very strong first stage, with the Kleibergen-Paap F -statistic being equal to 1,623. The coefficient estimate is $\rho = 0.92$ (s.e. = 0.01). Column 2 shows that the coefficient estimate is robust to including village fixed effects. In column 3, we collapse data by date and run a time-series regression with standard errors robust heteroskedasticity and autocorrelation up to 70 lags (HAC Newey-West). The coefficient falls slightly, but is still high at $\rho = 0.85$ (s.e. = 0.03). Overall, these results suggest almost all of changes in the wholesale price are passed through to farmers. These results are consistent with the findings of Gayi and Tsowou (2015), who show that cocoa farmer prices in several West African countries have been very responsive to world prices in the last two decades, with a pass-through rate of around 90 percent.

One caveat to these results is that this estimate of the pass-through rate does not include pass-through of value to farmers on non-price margins. Given the relatively

low frequency of international price movements, measuring pass-through in these terms would require collecting data on advance payments over multiple seasons. Therefore, the estimated pass-through rate, which is already quite high, is likely to be a lower bound of the pass-through one would measure when accounting for the value of advanced payment.¹³

IV. Estimating the Model Parameters

In this section, we use the experimental and quasi-experimental results to estimate the model parameters. The analysis proceeds in five steps. First, we recover trader differentiation, Γ , and supply slope, β from our experimental results. Second, we combine Γ with our quasi-experimental estimate of the pass-through rate to recover n . Third, we combine β , Γ , and n , to calculate own-price and cross-price supply elasticities, and quantify the price and quantity response to the experiment relative to a counterfactual without the experiment. Fourth, we discuss key assumptions of our approach and, where possible, validate these assumptions using the data. Fifth, we run simple counterfactual exercises to illustrate the importance of estimating all the market structure parameters.

A. Estimating Trader Differentiation (Γ) and Supply Slope (β) from the Experiment

To recover trader differentiation, Γ , and supply slope, β , we match the moments in equations (5) and (6) to their empirical analogs from the experiment. Here, we first discuss how to combine data on prices and advance payments into an effective price that summarizes the present value of the transaction for the farmer. We then present the main results from the estimation, substituting this effective prices for the price p_i in equation (1) of our model.

Preliminary Step: Treatment-Control Differences in Effective Prices.—The effective price paid to the farmer, p_i can be written as

$$(13) \quad p_i = \frac{\tilde{p}_i}{1 - \sigma_i(1 - \lambda)} \left(1 - \sigma_i \left(1 - \frac{\lambda}{\delta} \right) \right),$$

where \tilde{p}_i is the price paid by trader i , inferred from unit transaction values as described in Section IIIA; σ_i is the share transactions of trader i using advance payments; λ is the price discount accounting for interest (i.e., $\lambda = \frac{1}{1+r} < 1$); and δ is the farmer's discount factor, which captures the subjective value advance payment. Online Appendix Section B.1 derives the equation.¹⁴

¹³ Advance payment is the only margin of non-price competition on which we have data. Another potential margin could be that traders provide price insurance to farmers. Additional analysis shows the pass-through rate does not vary between treatment and control (p-value = 0.43). This suggests that treatment traders do not provide (additional) price insurance to farmers relative to control ones. This finding supports our approach in Section IVA, where we calculate the effective price using only price and advance payment provision.

¹⁴ We abstract from dynamic features of the farmer-trader relationship that may support the repayment of the advance. Accounting for these elements would require a repeated game framework, featuring multiple choice variables for the traders, each dependent on market structure, which does not lend itself easily to closed-form solutions

To obtain p_i , we require values for λ and δ . We recover these from the data, starting with a simple approach that uses cross-sectional variation in price and advance payment provision. We then show that quantitative results of our estimation are similar using different approaches that leverage different sources of variation, including an auxiliary experiment that measures farmers' subjective discount factor.

Baseline Approach: Cross-Sectional Variation in Farmer Prices and Advance Payment Provision.—As a starting point, we assume that the discount factor is the same for farmers and traders (i.e., $\delta = \lambda \Rightarrow p_i = \frac{\tilde{p}_i}{1 - \sigma_i(1 - \lambda)}$). In the first approach, we infer $\delta = \lambda$ from the baseline cross-sectional relationship between prices and advance payments. Since we observe payment amounts at the village level but not at the transaction level, our focus is on village-level average prices and on the share of farmers receiving advance payments in the village.¹⁵ Online Appendix Table B.1 reports the results of a regression of the price on the share of advance payments. Moving from a village where no farmer receives advance payments at baseline to a village where each farmer receives advance payments decreases shipment prices paid by the trader by approximately 150 leones from an average of 3,138, so $\delta = \lambda = 0.95$.

Having calibrated λ and δ , it is possible to compute the average treatment-control difference in effective prices, $p_T - p_C$. Panel A of Table 6 summarizes the results (columns 1–3). Average prices for control and treatment traders are: $\tilde{p}_C = 2,987$, $\tilde{p}_T = 2,982$ (from Table 2, column 2), $\sigma_C = 0.15$, $\sigma_T = 0.27$ (from Table 3, column 1). With these values, the average effective prices implied by equation (13) are $p_C = 3,010$ and $p_T = 3,022.8$ and the average treatment and control difference in effective prices is 12.8 leones, with 90 percent bootstrapped confidence intervals $[-17.8, 47.9]$.¹⁶

Sensitivity to Alternative Approaches to Valuing Advance Payments.—The baseline result is robust to alternative approaches to estimating λ and δ . Online Appendix Section B.2 presents details of the alternative strategies. Here, we provide a brief discussion. Panel B of Table 6 presents the results in columns 1–3. First, we assume again $\delta = \lambda$ and infer the value of advance payments from the covariance between treatment and control differences in prices and in advance payments. The

for the treatment-control differences, substantially complicating estimation. We assume instead that traders face a separable problem. First, they set their effective price conditional on the inverse supply curve and competition they face. Second, for a given effective price, they choose the combination of payments to be made at different times. We do not model this second step. When making their sale choices, farmers consider the effective price, not its composition. As a result the model captures a continuum of potential equilibrium contracts.

¹⁵ Village-level averages come from aggregating traders' baseline responses on prices, locations of activity, and number of suppliers. Here, we use villages as spatial unit to study the relationship between prices and advance payments. This is not inconsistent with our later discussion that villages may not be the relevant definition of market size. Our goal here is to estimate the slope of total payments with respect to advance payment provision. This requires partitioning farmers and using the partitions as data points. Villages are one of the many possible partitions, but a natural one to use (among other reasons, because we have covariates at the village level).

¹⁶ We treat the auxiliary parameter λ as a calibrated parameters and we do not account for its sampling variance when computing bootstrapped standard errors. Instead, we present sensitivity of our results to alternative methods to calibrate λ .

TABLE 6—ESTIMATES OF THE MODEL PARAMETERS

	λ (1)	δ (2)	$p_T - p_C$ (3)	Γ (4)	β (5)	n (6)
<i>Panel A. Main results</i>						
1. Cross-sectional variation in prices and credit	0.95	0.95	12.8 [-17.8, 47.9]	0.09 [-0.11, 0.47]	0.35 [0.24, 0.48]	12 [9.5, 21.2]
<i>Panel B. Sensitivity</i>						
2. Treatment heterogeneity in prices and credit	0.93	0.93	20.3 [-10.5, 55.6]	0.16 [-0.07, 0.59]	0.32 [0.22, 0.45]	12.9 [9.8, 25.4]
3. Calibration of interest rate	0.98	0.98	1.7 [-28.6, 36.7]	0.01 [-0.16, 0.32]	0.37 [0.26, 0.51]	11.1 [9.1, 17.1]
4. Farmer time-preference experiment	0.95	0.914	27.2 [-3.75, 62.6]	0.22 [-0.12, 0.72]	0.31 [0.21, 0.43]	13.8 [10.8, 32.15]
5. Only grade-A credit	0.92	0.92	19.6 [-11.0, 54.7]	0.15 [-0.07, 0.57]	0.33 [0.23, 0.45]	12.8 [9.8, 24.8]

Notes: The table presents results from the estimation in Section IV (further described in online Appendix Section B). The rows differ in the strategy to calibrate λ and δ . Panel A presents results of our baseline approach, in which we derive λ based on baseline cross-village variation in prices and credit and assume $\lambda = \delta$. Panel B presents results from four alternative approaches to compute λ and δ . For the parameters estimated in columns 3–6, we report in square brackets 90 percent confidence intervals from bootstrapping at the randomization pair level.

slope between the two response margins identifies their relative value, or how much less a trader who increases his advance payments needs to adjust his prices. The estimation suggests that when treatment traders provide credit but control traders do not, shipment prices would fall by 221 leones, from a baseline of 3,138 leones. Thus, $\lambda = 0.93$ and the difference in effective prices between treatment and control is 20.3 leones.

Second, we use the interest rate offered by Rural and Agricultural Banks to calibrate λ . As a lower bound for this value, we consider the rate of 2 percent per month. Assuming a loan duration of a month, i.e., approximately one-half of the duration of the intervention, $\lambda = 0.98$ (higher values of the interest rate would give values of λ closer to our baseline estimate). In this case the difference in effective prices between treatment and control traders is 1.7 leones.

Third, we allow the interest rate to differ from the subjective rate at which farmers' value future advances, or $\delta \neq \lambda$. To measure the farmer's discount factor, in November 2020 we conducted an additional incentivized lab-in-the-field experiment in three of the villages included in the main field experiment and during the same season. We asked farmers to make a number of binary choices between receiving money today or in the future. We estimate a median monthly subjective discount factor of $\delta = 0.914$. This rate is in line with recent experimental evidence on time preferences from other African countries (e.g., Balakrishnan, Haushofer, and Jakiela 2020). When we combine this estimate of δ with our baseline estimate of λ from cross-sectional variation in prices and credit (i.e., $\lambda = 0.95$), the difference in effective prices between treatment and control traders is 27.2 leones.

Fourth, we modify our baseline approach to deal with the observation that some of the advance payments may have been given with the expectation that a farmer would deliver non-grade A cocoa (as per our discussion in Section IIIA). For this purpose, we scale down both the baseline village-level credit share and the credit shares in

each treatment group during the experiment by the share of grade A transactions. We obtain $\lambda = 0.92$, $\sigma_C = 0.068$, $\sigma_T = 0.17$. In turn, the implied difference in effective prices between treatment and control traders is 19.6 leones $[-11.0, 54.7]$. Through a similar procedure, the difference in effective prices for grades B and C is shown to be 31.1 when pooled together, and 37.8 when restricting to grade B only. These values are within the 90 percent confidence interval of the treatment-control difference in effective prices for grade A.

Estimating Γ and β .—We can now estimate Γ and β by matching the moments in equations (5) and (6) to their empirical analogs, using the difference in *effective* prices in equation (5). Intuitively, we recover Γ (the degree of differentiation among traders) from the price treatment-control difference and β (the slope of the trader's inverse weekly supply) from the quantity difference.

Columns 4 and 5 of Table 6 report the result. The first row shows results with our baseline approach to compute effective prices ($\lambda = \delta = 0.95$). We obtain $\Gamma = 0.09$ (90% C.I. $[-0.11, 0.47]$) and $\beta = 0.35$ (90% C.I. $[0.24, 0.48]$).¹⁷

The remaining rows in Table 6 illustrate the sensitivity of these estimates to alternative approaches to valuing advance payments. Estimates of trader differentiation Γ range between 0.01 and 0.22, with the highest value when calibrating the farmer's discount factor from the auxiliary experiment, which also gives the highest difference in effective prices. This result illustrates how the value of credit is enhanced when credit markets are incomplete and $\delta < \lambda$.¹⁸ Estimates of the inverse supply slope β span between 0.31 and 0.37.

Overall, these results suggest that regardless of how advance payments are valued, traders appear fairly undifferentiated. This result is consistent with other empirical findings from sub-Saharan Africa (Fisman and Raturi 2004; Ghani and Reed 2022) and from China (Fabbri and Klapper 2016), which show that buyers provide relatively more trade credit to suppliers with whom they have relatively less bargaining power. One explanation for this result could be the existence of customary legal enforcement. In this setting, disputes can be brought before a customary law court run by the Paramount Chief and his or her deputies, which has the authority to levy penalties for breach of contractual obligations. The threat of enforcement in such courts may obviate the need for relational contracts requiring market power to sustain credit contracts. Another is that competition reduces holdup concerns on the lender side and it may thus increase borrowers' incentives to establish creditworthiness (as in Fisman and Raturi 2004).

¹⁷From Γ and β , it is then straightforward to obtain $\gamma = (1 - \Gamma) * \beta = 0.318$

¹⁸It is also useful to quantify how large the increase in the value of advance payments would have to be to make Γ significant at 5 percent: simulations show that this would occur if moving from a village where no farmer receives advance payments a village where each farmer receives advance payments decreased shipment prices by 380 leones (2.5 times our baseline estimate), in which case $\lambda = 0.88$ and $\Gamma = 0.36$.

B. Estimating the Number of Competitors (n) from Quasi-Experimental Variation in Cocoa World Prices

We use the quasi-experimental estimate of the pass-through rate of Section IIIB to estimate the number of buyers effectively competing for supply (equation (9)).

In the average village, we observed 7.8 traders operating, already perhaps a large number. Using our estimate of $\rho = 0.92$ from Table 5, and an estimate of Γ using the baseline approach to valuing advance payments delivers an estimate of $n = 12$ with 90 percent C.I. [9.5, 21.2] (first row of Table 6, column 6). These estimates of n imply that, according to the model, traders behave as if the number of their competitors were about 40 percent higher than observed in the average village.

This result confirms the intuition that village markets operate as if they are highly contestable: the option to sell to other traders shapes competition, not the actual number of traders actually purchasing from each farmer. Sensitivity analysis in the remaining rows of Table 6 shows a range of estimates of n between 11.1 and 13.8, suggesting that the result is robust across alternative approaches to valuing advance payment.

We obtain similar results when using alternative moments from the model, in the spirit of an overidentification test. Specifically, we derive theoretical expressions for the *percent* difference in prices and quantities between treatment and control traders and match them to their empirical counterparts. This approach yields estimates which are quite similar; for instance, when using $\lambda = 0.95$, we obtain $\Gamma = 0.097$ and $n = 11.07$. Online Appendix Figures C.1 and C.2 also show that, in the case of model misspecification, estimation using absolute or percent differences would yield considerably different estimates. Online Appendix Section C provides details.

Consistent with the idea that the number of traders observed operating in a village do not necessarily measure the market structure, we do not detect statistically significant impacts of the number of treated traders in the village on the treatment-control differences in prices, advance payments, and quantities.

C. Supply Elasticities and the Response to the Experiment

With the model's estimated parameters (Γ, β, n) in hand, one can calculate: (i) own-price and cross-price elasticities (from equations (7) and (8)); and (ii) the impact of the experiment, relative to a counterfactual without the experiment.¹⁹

Own- and Cross-Price Supply Elasticities.—Using the baseline parameter estimates and average prices and weekly quantities, we obtain the own- and cross-price elasticities facing each trader. Note results are similar when using counterfactual prices and quantities in the absence of the experiment, which we derive next.

The own-price elasticity is very high, $\eta_{ii} = 327$. This is exactly what we would expect in a competitive market. A small increase in the prices of one of the competitors leads to a large increase in supply. In the limit case of perfect competition with

¹⁹Note that if one were sure about market boundaries, one could count the number of firms within a relevant geographic market and use that as an input to compute elasticities.

atomistic firms, this value would be infinity. The cross-price elasticity is $\eta_{ji} = -29$, which implies that if one of the competitors increase the price by 1 percent, each of the other 11 competitors loses 29 percent of their supply. This is consistent with a very competitive market.

The Impact of the Experiment.—Through the lens of the model, we can quantify the impact of the randomized subsidy on prices and quantities of control and treatment traders, relative to counterfactual prices and quantities in the absence of the experiment. Without SUTVA, the counterfactual is not observed directly in the experimental control group, and must be inferred from theory. The main results of this calculation are described here, while online Appendix Section D provides the equations.

The analysis proceeds in two steps. First, we calculate the effect of the subsidy on effective prices paid by both treatment and control traders, relative to a counterfactual without the experiment. The derivatives of the prices of treatment and control traders with respect to the subsidy value are pinned down by Γ, n , and μ . Recall μ is the share of treatment traders in the market, or 0.2. Using results from panel A of Table 6, we find that, in response to a subsidy of 150 leones per pound, control traders increased (effective) prices by 24.95 leones and treatment traders by 37.75 (hence, a difference of 12.8 leones). Online Appendix Section F.2 shows, for the estimated values of the competition parameters, the increase in the treatment and control prices in response to a unit subsidy, relative to the scenario without the experiment, as a function of the share of treated traders, $\mu \in (0, 1)$.

Second, using the estimate of β , as well as Γ, n , and μ , we compute the quantity responses to the experiment. In response to the subsidy, treatment traders increased supply by 324 pounds (a 174 percent increase relative to a counterfactual without the experiment) and control traders reduced supply by 72 pounds (a 38 percent decrease). This makes sense when recalling that there are four non-treated traders for each treated trader. Aggregate supply increased only by 3.8 percent. Eighty-nine percent of the increase in quantity for treatment traders comes from market stealing, a result reminiscent of Rotemberg (2019). A priori, one might have expected the majority of the increase to have come from market stealing, given that the experiment was implemented at harvest time and farmers had limited options to increase their supply in response to the price changes (e.g., reducing processing losses). By this time, production capacity is fixed by the number of trees that have been planted.

D. Discussion of Assumptions and Model Validation

The model presented in Section I makes a number of assumptions. To be transparent, we discuss these assumptions here and, where possible, provide additional evidence in their support.

Conduct.—Our model assumes a specific equilibrium concept, Nash-in-quantities. Here we provide evidence against alternative hypotheses. An alternative model is a segmented monopsony, in which there are many traders, but each prices as a monopsonist facing a distinct set of farmers. The small difference in (effective)

prices between treatment and control could reflect a scenario where each trader has a very high degree of market power but, given some alternative (i.e., nonlinear) functional form of farmer supply, does not raise the price in response to the subsidy. The large quantity responses to treatment and the high degree of pass-through to common shocks provide initial evidence against this interpretation. Analysis of the implied elasticities provides additional evidence against segmented monopsony, under a *general* supply curve. A monopsonistic trader with general inverse supply curve $p(q)$ will price following Lerner's condition: $p = v \frac{\epsilon}{\epsilon + 1}$, where ϵ is the own price elasticity. Assuming this pricing condition holds and recalling that $v_C = v, v_T = v + s$, one recovers ϵ from the treatment-control difference in prices, $p_T - p_C = s \frac{\epsilon}{\epsilon + 1}$. This gives a very small elasticity: $\epsilon = 0.093$. However, under segmented monopsony, one can also estimate ϵ from the ratio in the percent treatment-control differences in quantity and prices: $\frac{(q_T - q_C)/q_C}{(p_T - p_C)/p_C}$. In this case, given the large quantity difference, the estimated elasticity would be very high, $\epsilon = 812$. The inconsistency between these estimates contradicts the assumption of segmented monopsony.

A second alternative model is one in which traders operate in the same market, but have formed a cartel that can price as a monopsonist. This model is inconsistent with our finding a high pass-through rate, and large implied number of firms in the market. Were traders pricing as a cartel, the number of firms identified by the pass-through rate would be one. Setting aside the quasi-experimental evidence from the pass-through rate, the fact that treatment-control differences are small for prices could be consistent with treatment and control buyers forming a cartel to take advantage of the subsidy by passing quantity to treatment from control traders. Collusion is however inconsistent with the large differential response of treatment traders in terms of advance payment provision. In addition, we note that collusion of this form would require not just an agreement between a treatment and a control trader to game the incentive system, but also collaboration among treatment traders (since otherwise a non-colluding treatment trader could steal the suppliers of the treatment-control pair cartel). The latter is a more demanding form of collusion and it faces the standard enforcement problems of a cartel.

Replicating our main estimation procedure using Bertrand competition, while retaining other assumptions on producers and buyers, delivers unrealistic parameter values (i.e., a value of Γ larger than 1). This suggests that quantity may be the relevant strategic choice variable in the setting. As it is well known, Cournot outcomes can also be interpreted as reduced-form outcomes for price competition with quantity constraints (Kreps and Scheinkman 1983). Quantity constraints arising from only being able to carry so many bags on a truck or motorcycle are relevant in this setting.

One might also posit a model of monopsonistic competition (adapted from the more common monopolistic competition case): Dixit and Stiglitz (1977) predicts a markdown on the subsidy equal to the markdown observed in the baseline data; Ottaviano, Tabuchi, and Thisse (2002) predicts a difference between treatment and control traders of one-half of the subsidy value. Neither of these predictions finds support in the data. For instance, farmer prices are on average 92 percent

of the wholesaler prices. Under constant markdown case, this would imply a difference in effective prices of at least 135 leones between treatment and control traders.

Functional Forms.—The model assumes linear supply, rather than working with an unrestricted supply elasticity. Among other reasons, the use of linear supply may be a concern because linear supply can be microfounded with a representative agent approach, but not with a discrete choice problem (see, e.g., Jaffe and Weyl 2010; Armstrong and Vickers 2015).

It is possible to examine sensitivity of the results to this assumption. Consider an alternative inverse supply with curvature ζ : $p_i = \alpha + \beta q_i^\zeta + \gamma \sum_{j \neq i} q_j^\zeta$ (in the baseline linear inverse supply of equation (1), $\zeta = 1$). Using the first-order conditions and the price and quantity levels and treatment-control differences as estimating moments, we can recover the vector of parameters $(\beta, \Gamma, \alpha, \nu)$ as a function of the curvature parameter ζ . This analysis suggests that our key result of low trader differentiation is robust to relaxing the assumption of linear supply. Our benchmark $\zeta = 1$ corresponds to $\nu = 3,050$, which is very close to the sum of the effective price in the control group (3,010) and the average transport costs (49, as we discuss in the next paragraph). At $\zeta = .9$, ν is equal to 3,059. Higher values of ν , which imply traders get a larger share of surplus, imply lower ζ and, crucially, lower Γ (for instance, the upper bound of ν equal to the average wholesaler price, or 3,260 leones per pound, corresponds to $\zeta = 0.29$ and $\Gamma = 0.03$). Higher values of ζ are unlikely because they would imply that traders systematically make losses. For instance, when $\zeta = 2$, $\nu = 3,017$. Even in this extreme case, Γ is still low (0.19).

Another assumption is that estimated ν and p do not depend on quantities, ruling out nonlinear pricing and other nonconstant trader marginal costs (see, e.g., Attanasio and Pastorino 2020). We also assume that the only cost for the trader is the crop purchase cost and that this cost is linear. This is a reasonable approximation given that the crop purchase costs are around 90 percent of resale prices. However, traders do bear other costs, for instance to transport the crop. Our estimates of the differentiation rate are intuitively robust to the introduction of other constant marginal costs. Column 1 in online Appendix Table F.2 shows that unit transport costs of treatment traders do change slightly in response to the subsidy (a reduction of approximately 14 leones, from a control mean of 49 leones). Column 2 of the same table suggests that they are more likely to use a truck to transport the crop, instead of motorbikes. In a simple twist of the model, the reduction in unit costs for treatment traders has the same effect of an increase in the subsidy value (i.e., from 150 to 164 leones). Accounting for the change in transport cost, our estimate of Γ would slightly decrease (from 0.092 to 0.085).²⁰

Representative Agents.—Agents are assumed to be symmetric, aside from the heterogeneity introduced by the experiment (i.e., the experimental subsidy, s).

²⁰Explicitly modeling a nonlinear (e.g., quadratic) cost would complicate the relationship between the treatment-control differences and the parameters of interest. One would need additional moments (e.g., higher-order powers of the treatment-control differences) to achieve identification.

Online Appendix Section E.1 shows how the model can be extended to include heterogeneity in traders' marginal revenue and a heterogeneous differentiation rate across different pairs of traders. In principle, one could estimate Γ separately in each location and then compute the average of the parameters across villages. In practice, for our specific experiment, estimating separate parameters in each location (using information on the main village of provenience of the cocoa in the shipment) delivers results that are too noisy to be useful.²¹ A related concern is the presence of non-study traders. These comprise about 60 percent of the traders operating in the study region and, in principle, they could be different from the study traders (control and treatment) at baseline. The model presented in Section I is robust to the presence of such traders.²²

Timing.—Our model is static while the interaction between farmers and traders unfolds over an entire season. The experiment only ran until the end of the harvest season. Traders and farmers may have behaved differently in a multi-season trial. Again, it is plausible to assume that in a longer experiment the degree of differentiation would be even lower. For instance, in a longer experiment, farmers may have been more willing to switch to other buyers. Future research could assess whether varying the duration of the experiment leads to substantially different results. With this caveat in mind, we however believe that running the experiment until the end of the season was a reasonable length. The subsequent harvest season follows seven to eight months of inactivity and new trading relationships may potentially arise during that period. In addition, the high pass-through rate we described in Section IIIB suggests that traders respond to high-frequency price changes, which are likely to be more transitory than our experimental season-long subsidy. The fact that the experiment lasted until the end of the season also suggests that traders had enough time to learn about the subsidy of their competitors, in line with the assumption of perfect information in the model. We also observe that the variation in prices induced by our experiment is less transitory than daily or weekly price variation used in many studies of pass-through.

E. Counterfactual Experiments

Estimates of the differentiation rate and effective number of firms in the market allow for the analysis of the impacts of subsidies that target subsets of firms in the market, a feature of many industrial (agricultural) policies. When subsidies are offered only to a subset of firms, they have direct effects through changes in the prices paid by treated firms, and indirect effects through the strategic response of untreated firms. The model may be used to simulate the general equilibrium effect

²¹For instance, with few observations per village, the treatment-control difference in effective prices is often either negative or larger than 150 leones (i.e., the subsidy value), which in both cases implies a negative value of Γ . However, it is reassuring that when we include village fixed effects in the regressions with pooled data, results are very similar to the ones presented in the text.

²²Online Appendix Section E.2 presents an extension of the model where only a share σ of traders is included in the study, and thus study treatments are a share $\sigma\mu$ of traders. Non-study traders have a resale price, v' , that possibly differs from the study traders' one, v . The equilibrium treatment-control price difference Δp (equation (5)) is unchanged.

FIGURE 4. COUNTERFACTUAL EXPERIMENTS: RETURN ON INVESTMENT BY Γ

Notes: The graphs show the return on investment (ROI) in the three counterfactuals described in Section IVE. The ROI is defined as the ratio between the additional farmer revenues induced by the intervention and the cost of the intervention. Panels A and B focus on the case of homogeneous traders. Panel A shows the ROI where 20 percent of traders are subsidized ($\mu = 0.2$). Panel B shows the ratio of the ROI with $\mu = 0.8$ to $\mu = 0.2$. In panel C, one-half of the traders have a 5 percent higher resale price and are therefore “large.” The figure compares the ROI when half of both types of traders get the subsidy ($\mu_L = \mu_S = 0.5$) and when only large traders get the subsidy ($\mu_L = 1, \mu_S = 0$). In the three panels, these outcomes are plotted as a function of Γ , while keeping the pass-through rate constant at 0.91 and adjusting the number of firms, n , according to equation (9).

of the policy, for different shares of subsidized firms. For example, in our context, a government might wish to subsidize agricultural output by raising the wholesale price. The model facilitates different subsidy interventions in terms of their *return on investment*: the ratio of benefits in terms of incremental farmer revenues and costs, or total expenditure on the subsidy.

Figure 4 reports the return on investment in three counterfactual scenarios to illustrate the importance of the differentiation parameter in this policy analysis. In each of the figures, we vary Γ , while keeping the pass-through rate ρ constant at 0.91, and thus adjusting n according to equation (9). Panel A shows that the return on investment of an intervention that provides subsidies to one-fifth of the traders (similar to our experiment) is increasing on Γ , with returns more than eight times as high for Γ close to 1 than for Γ close to 0. Panel B shows that the additional benefits of subsidizing more traders ($\mu = 0.8$ versus $\mu = 0.2$) are decreasing in Γ : the high-intensity intervention gives 20 percent higher returns at low values of Γ , but similar returns at high values of Γ . In panel C, we consider two types of traders, each comprising one-half of the traders, which differ in the resale value and thus

in the equilibrium quantity purchased (at $\Gamma = 0.09$, the difference in quantity is about five-fold). We consider an intervention that subsidizes half of each type of traders and one that subsidizes all of the large traders (and none of the small ones). The former has always higher returns, but its relative benefits are decreasing in Γ . These counterfactuals highlight the importance of estimating separately the two parameters shaping pass-through (i.e., Γ, n).

V. Conclusion

The potential outcomes framework for experimental analysis is not valid when treatment and control agents interact strategically, a feature of settings in which experimental subjects are participants in the same market.

We have shown that, when SUTVA fails, individual-level randomized subsidies can identify market structure parameters. The average difference in prices paid by treatment and control agents informs an intuitive test of the degree of differentiation between them: only if agents are differentiated can there be systematic differences in the average prices paid by subsidized and nonsubsidized agents. Combining an estimate of differentiation with the pass-through rate reveals the number of firms competing in the market in a Nash-in-quantities equilibrium.

Overall, the evidence suggests the Sierra Leone farm-gate cocoa market is highly competitive. The pass-through rate is high, farm-gate traders exhibit a low degree of differentiation, and own-price and cross-price elasticities are high. However, while these findings are suggestive of an overall high degree of competition at the farm gate, firms at downstream levels the supply chain not studied here (i.e., wholesalers, exporters) may have substantially more pricing power. In Sierra Leone, where exportation is organized by the private sector, Figure 2 showed that, though wholesaler prices respond somewhat to changes in the international price, pass-through is lower at that stage of the value chain. Identifying whether this lower level of price pass-through may be explained by weak competition among wholesalers or exporters is an important area for future research.
