Media Attention and Betting Markets

Stefan Legge[†] Lukas Schmid[‡]

June 3, 2016

Abstract

This paper investigates whether biased media attention affects perceptions about future events. We use data on World Cup tournaments in alpine skiing for the period of 1992–2014 and exploit close races as a source of randomness for ranking positions. Since the allocation of media attention is skewed towards the winner and athletes on the podium, we can estimate the causal effect of media attention. Our results document that ranking schemes generate sharp discontinuities in media attention even in close competitions. However, both regression discontinuity and instrumental variables estimates reveal that biased media attention neither affects prices nor quantities in the betting market. We conduct a series of robustness tests to explore the sensitivity of our results.

1 Introduction

There is a large and growing body of literature documenting the media's impact on economic, political, and social outcomes (DellaVigna and La Ferrara, 2015; Strömberg, 2015). In particular, prior research has pointed out that media outlets play a key role in reducing complex information for consumers with limited time resources (Falkinger, 2007). Hence the media focus on certain events, groups, and individuals which in turn has been shown to affect decisions and behavior in various domains, namely which political candidates are elected (Epstein and Robertson, 2015), how politicians react to disasters (Eisensee and Strömberg, 2007), which issues voters care about (Mastrorocco and Minale, 2016), what family size people prefer (Jensen and Oster, 2009; La Ferrara, Chong and Duryea, 2012), or what consumption bundles consumers demand (Bursztyn and Cantoni, 2016).

While this evidence suggests that the media can influence what individuals think of the past and the present, we know surprisingly little about its impact on what people think about the future. In order to study individual perceptions about future events, economists typically use betting markets because they provide an incentive-compatible way for individuals to truthfully reveal their expectations (Wolfers and Zitzewitz, 2006). However, several empirical studies document that behavioral biases or risk-loving preferences might lead to a situation in which prediction markets do not reveal true probabilities (Friedman and Savage, 1948; Kahneman and Tversky, 1979; Snowberg and Wolfers, 2010). Another important and unexplored explanation for why betting odds deviate from true probabilities, however, is that bettors make decisions using information they receive from the media. If media outlets allocate significantly more attention to some individuals than to others, expectations about future events related to these individuals might change. For example, bettors might overestimate future prospects of politicians who receive the lion's share of media coverage after a debate. Similarly, athletes who succeed in one tournament and are covered extensively by media outlets may be perceived more likely to succeed in subsequent tournaments. The methodological challenge researchers face when estimating such an effect of media attention on expectations is that the allocation of attention across individuals is not randomized but correlated with unobserved factors like skill or talent.

This paper offers a novel identification strategy to estimate the causal effects of media attention on betting markets by analyzing close competitions in World Cup alpine skiing from 1992–2014. For several reasons this setting provides a unique real-world natural experiment. First, there are considerable differences in how much media attention athletes receive. Those individuals at the top of the classification typically receive the bulk of attention. Second, unlike in most other settings with ranking schemes, our data set enables us to observe the same individual numerous times. Hence we can compare the amount of attention they receive when they achieve or miss a top ranking position by including athlete-fixed effects. Third, in alpine skiing small time differences resulting from random shocks, like weather and snow conditions, can manipulate ranking positions. Hence luck is more prevalent in skiing than in other sports such as, for example, golf (Connolly and Rendleman, 2008). In close races it is often a tiny margin —a few hundredths of a second— that determines whether an athlete finishes first or second, third or fourth, or even sixth or tenth. Assuming such small time differences to reflect random noise allows us to argue that those athletes who achieved a higher rank in a close race quasi-randomly received more media attention. Hence we can explore the causal effects of media coverage on betting market outcomes for these athletes.

Our findings suggest that top-ranked individuals receive 31.5% more media attention compared to athletes with an arguably similar performance who barely missed the highest ranking positions. We also document that betting odds generally decrease with both ranking positions and media attention. However, when focusing on close races for which ranking positions and thus media attention are allocated randomly, we find no discontinuity in betting market outcomes. This suggests that media attention does not cause betting market participants to change their beliefs about the future prospects of athletes. In contrast, we find that betting markets are efficient in the sense that observed odds match estimated true probabilities. Only when extending the sample to include athletes relatively far away from top ranking positions, we find a significant difference in both true probabilities and betting odds between top ranked and not top ranked athletes.

¹Didier Cuche's last seconds in the 2010 Vancouver Olympics downhill race exemplify that small time differences can result in large differences in ranking positions. Lagging only 0.06 seconds behind leader Didier Défago, Cuche was second at the beginning of the last ten seconds. But Cuche did not optimally pass the last gate and finished sixth, trailing the winner Défago by 0.36 seconds.

We conduct a series of robustness checks to assess the validity of our findings. First, we show that there are no systematic differences in pre-determined covariates between those who achieve, for instance, a podium finish in a close race and those who barely miss it. This supports our empirical strategy that uses random top ranks as exogenous manipulation of media attention. Second, our results are shown to be robust to the choice of bandwidth for the definition of random top ranks. Third, we document that higher ranking positions do not causally change an athlete's risk-taking behavior or performance in subsequent races. Fourth, we point out that our main results from reduced form estimations do not change if we estimate instrumental variables regressions. Finally, we show that our core findings on media attention are not confined to the Swiss newspaper archive 'Swissdox' but generalize to the American-based 'NewsLibrary'.

Our paper provides several novelties. First, to our knowledge, we are the first to provide causal evidence that rankings generate significant differences in media attention. After a close race, newspapers focus on those athletes who achieved the top positions in the ranking even if performance differences were tiny. A central explanation for why media outlets focus on individuals who achieved a top rank is that they compete for consumers in an information-rich economy (Falkinger, 2007, 2008). Recent advances in information technology have dramatically increased the supply of information. Newspapers and TV programs respond to this by focusing particularly on the most relevant and successful individuals. This form of biased media attention is relevant because previous research documents that it can affect election outcomes (DellaVigna and Kaplan, 2007; Epstein and Robertson, 2015) as well as consumer preferences (Gentzkow and Shapiro, 2010).

Second, we show that media attention has no effect on betting behavior. This finding adds to prior research on how individuals deal with rankings and ratings. Salganik, Dodds and Watts (2006) find that the availability of music ratings increases downloads of already successful songs. Similarly, Feenberg et al. (2015) show that NBER working papers which are listed first in the weekly newsletter receive substantially more views and citations. Furthermore, the use of explicit ranking schemes has been found to affect how consumers choose

restaurants (Luca, 2016).² Our findings, however, suggest that the allocation of attention does not affect betting market outcomes such as odds or the number of bets placed. We argue that the incentive structure and efficiency of the market provide an explanation for this observation.

Third, our results show that professional sport athletes exhibit substantial serial correlation in their performance but do not change their risk behavior or performance following a top ranking position in one tournament. Previous research has pointed out that lagging behind in a ranking increases risk-taking and lowers final performance (Genakos and Pagliero, 2012).³ Furthermore, our findings contribute to a sizable literature on the so-called hot-hands effect (Gilovich, Vallone and Tversky, 1985; Green and Zwiebel, 2015; Miller and Sanjurjo, 2015). In particular, we find that one-time successes do not have a causal positive effect on subsequent performance. Finally, several studies show that the mere provision of a relative ranking position can affect student performance (Tran and Zeckhauser, 2012; Kuhnen and Tymula, 2012) as well as employee satisfaction (Card et al., 2012). The key difference between our work and these earlier studies is that we analyze the effect of rankings using a setting in which ranking positions are arguably randomized in close competitions. In addition, having more than twenty years of data allows us to observe the same individual multiple times in both the treatment and control group.

The paper proceeds as follows. Section 2 presents general information on World Cup alpine skiing as well as descriptive statistics on our dataset. This comprises a description of the data on media attention as well as the betting market. Section 3 discusses the problem of identifying the causal effect of media attention on betting market outcomes. We explain the concept of the quasi-random allocation of top ranks and how this can be used to overcome the identification problem. Section 4 presents our empirical findings on how media attention affects betting market outcomes. This includes a series of robustness checks. Finally, Section 5 concludes.

²Further empirical evidence on the powerful impact of rankings in the field of M&A markets has been provided by Derrien and Dessaint (2015).

³In a laboratory setting, Gill et al. (2016) document a U-shaped relationship between ranking position and effort, reflecting both 'first-place loving' and 'last-place loathing'.

2 Data

Our data set provides an opportunity to study the behavior of World Cup athletes, media outlets, and bettors in an environment with large stakes and fierce competition.⁴ In this section, we first provide background information on World Cup skiing competitions. Moreover, we describe our data set which includes information on race results, media attention and betting market outcomes for all tournaments.⁵

2.1 World Cup Alpine Ski Tournaments

The origins of alpine skiing competitions go back to the 1930s when European ski clubs, most prominently in Switzerland, Austria, and Germany, decided to organize races. In 1967, the Fédération Internationale de Ski (FIS) decided to bring these separate events together and launched the FIS World Cup. Today, alpine skiing competitions enjoy great popularity, particularly in Europe. The downhill race in Wengen (Switzerland), for instance, has been followed by a TV audience of over one million viewers in Switzerland (one eighth of the country's population) for each of the races between 2007 and 2012 (Ski World Cup Wengen, 2012). A similar appeal comes from the downhill and slalom races in Kitzbühl, each of which is watched by more than 1.3 million Austrians. In addition to large audiences, sizable prize money is also par for the course. Among all top-ten athletes in the season of 2012/2013, the prize money sums up to \$4.4 million for men and \$4.2 million for women (FIS 2013). However, the distribution of income in prize money is highly skewed. The highest income among male athletes was \$589,009 and among females it was \$771,289. Number ten of the prize money ranking earned only \$109,010 and \$126,858, respectively. A considerable fraction of 76% of male and 80% of female athletes earned less than \$50,000.6

⁴Klaassen and Magnus (2009) discuss the usefulness of sports data to examine behavioral questions. DellaVigna (2009) provides a summary of research documenting that behavioral biases may disappear among experienced individuals.

⁵While our data set on World Cup tournaments and media attention includes all races from 1992–2014, the analysis of betting markets is restricted to the period 2006–2014 because we only have the respective data for this period.

⁶Note that these prizes are large enough to incentivize athletes to exert high effort but not too large to cause one-time winners to reduce their subsequent efforts. Besides the prize money, top ranks in World Cup races can also lead to better sponsorship contracts. While there is no reliable data on sponsorship incomes,

The goal of alpine skiing is to slide down a race course in the fastest overall time. Each course consists of a series of gates. All of them have to be passed correctly, so that all athletes run the same course. The five disciplines differ in terms of the vertical and horizontal distance between the gates as well as the horizontal distance between start and finish. The average speed of a downhill racer is about 100 km/h, while in slalom races the athletes usually achieve about 40 km/h.

2.2 Data on World Cup Skiing

We use a panel data set on 473 male and 428 female athletes in all 1,587 World Cup ski races for the period of 1992–2014. The data set includes information on whether an athlete finished the race, the exact result in hundredths of a second, as well as gender, age, and the discipline of competition.⁷ The panel structure allows us to measure each athlete's performance in subsequent races. In total, our data set contains 23,761 observations when the unit of observation is an athlete in a specific race.

— Table 1 about here —

Table 1 reports descriptive statistics for the data we use in the empirical analysis. In part (I), we show information on all athletes competing in World Cup tournaments for the period of 1992–2014. Since we focus on top ranks, the sample is restricted to all athletes in the top fifteen. The share of athletes on the podium is 20.3% of the total number of observations. Observations for today's race are more numerous than observations for past and future performance because we only use outcomes within season, which results in missing values for the first and last race of the season for each race discipline. Furthermore, we cannot use observations at the end of the season because we would lack future performance and betting odds. Taken together, these account for around a fourth of the total observations. Finally, the number of observations is reduced because only 82% of those athletes

insiders estimate that in the case of top athletes, this source of income makes up three to four times the amount of prize money.

⁷Race times are actually measured more precisely than stated in official reports. For any time in hundredths of a second, the measurement was accurate at the millisecond level.

who compete in the next race finish the race and get a positive race time. It is important to note that competition in alpine skiing is fierce. Only few junior athletes make it to the World Cup team and, among them, only a small group is successful. From our total sample, only about seven percent of the athletes ever won a race during their entire career. This suggests that only a small set of competitors is very successful over a lifespan which is in line with empirical evidence concerning the presence of superstars in music, entertainment, and academia (Rosen, 1981; Hamlen, 1991).

2.3 Data on Media Attention

We complement our data set of individual World Cup tournament results with information on media attention and betting odds. For the former, we scraped data from the Swiss newspaper database "Swissdox" for various time horizons before and after the race. Overall, the Swissdox database covers more than 200 newspapers, almost all of which for the entire time period of 1992–2014. Our search queries included an athlete's name and the time horizon of the search. We measure media attention by the number of articles mentioning the athlete's name. Part (II) of Table 1 shows descriptive statistics for the number of articles published at various points in time. Not surprisingly, there are more articles about a particular athlete the more we extend the time window.

In Figure 1, we show the distribution of media attention across ranking positions. Panel (a) depicts the average number of newspaper articles that mention an athlete's name on the day after the competition. While winners are mentioned in 17.8 articles on average, athletes ranked second or third get an average media presence of 13.0 and 11.2 articles, respectively. The average number of articles is considerably lower for other athletes, namely 5.4 for athletes on positions four to ten and 3.7 for athletes on position eleven to fifteen. The pattern in media attention is notably similar when focusing on media attention during the week or month following the race.⁹

⁸The most successful athletes in the history of alpine skiing are Ingemar Stenmark (Sweden, 1973–1989) with 86 victories and Annamarie Moser-Proell (Austria, 1969–1980) with 62 victories.

⁹Note that the distribution of media attention we obtain using our scraping algorithm yields very similar results for other fields of sports, such as Formula 1 competitions as illustrated by Figure A.2 in the Appendix.

— Figure 1 about here —

Because the source of our media data, Swissdox, may be biased towards Swiss and German-speaking athletes, we repeat the scraping procedure for "NewsLibrary", a US-based online news database that includes more than 4,000 outlets. In the robustness section we use this data to show that we obtain similar regression results for the media attention, irrespective of which source of media data we use. In addition, Figure A.1 in the Appendix illustrates that the distribution of media attention across ranking positions is almost identical among newspapers covered by NewsLibrary when compared to newspapers covered by Swissdox in Panel (a) of Figure 1. The reason why we use Swissdox data for our main analysis is that the NewsLibrary search often finds mainly articles with ranking lists. In contrast, using newspapers in Swissdox, we find mostly specific reports on World Cup skiing. Since mere ranking lists are not the kind of media attention that we are primarily interested in, we employ Swissdox data for our main analysis. Nevertheless, it is important to stress that we obtain similar distributions of media attention from both sources.

2.4 Data on Betting Behavior

In order to obtain information on betting market outcomes, we collected data from the world's largest internet betting exchange "Betfair". We focus exclusively on bets for a specific athlete to win the next race. This corresponds to about three quarters of all bets. This set of data includes a total of 77,202 individual bet observations and is available for the period 2006-2014. Note that each individual observation corresponds to a bet offered for a specific event (e.g., athlete A to win the next tournament) with a specific odd. For our analysis, we use three different odds for each athlete-event combination.

— Figure 2 about here —

As illustrated in Figure 2, the betting market for the subsequent race opens after a given race t. At the beginning, a bet for each athlete who is likely to compete in race t+1 is offered

¹⁰In our sample, 75.4% of all bets and 72.0% of the total volume are placed on who will win a race (the group we focus on in our study). In contrast, only 2.4% of all bets and 1.8% of the total volume are placed on the winner of the overall World Cup. The rest of bets is placed on a variety of different outcomes (for example, whether athlete A performs better than athlete B).

at an *initial odd*. Over time, this odd changes due to new information (e.g., a competitor being injured) or because of altered demand for bets. If, for example, the demand for a bet on athlete A surges, the odd offered by the betting agency for this athlete will go down. At some point prior to the race t+1, the betting market closes and we record the *final odd* for each athlete. Hence, we have an initial and a final odd for each athlete and event. In addition, we aggregate all individual odds for a specific event and athlete to obtain an *average odd*. In the robustness section, we use all three odds to investigate how media attention affects the betting market at different points in time.

Panel (b) of Figure 1 illustrates the distribution of the inverse average betting odds across ranking positions. Betting odds are what a bettor gets paid for a bet of one unit if the specific event of the bet is realized. For example, a betting odd of 1.2 on athlete A means that the bettor collects \$1.2 for a one-dollar-bet if athlete A actually wins the competition. This translates into an inverse odd of 1/1.2=0.833 that reflects the implied probability that athlete A wins the race. Because these implied probabilities are directly comparable to the true probabilities that athlete A wins the race, we will henceforth use the reciprocal odd as our main measure of betting odds.

Similar to the distribution of media attention, we note substantial differences in average betting odds across ranks. While winners of the current race have an average implied probability of 0.25 in the subsequent race (which is equivalent to paying off \$4 for each dollar invested), a bet on one of the other athletes has an implied probability of about 0.14. Placing a bet on an athlete on position four to fifteen yields an average implied probability that is substantially smaller (0.08). As expected, those finishing on the top ranks in a tournament receive significantly more bets—both in terms of the number of bets and total money volume—in the subsequent tournament.

— Figure 3 about here —

It is important to understand who actually participates in the alpine skiing betting market. The total betting volume in our data set is \$1.7 million. Figure 3 depicts the distribution of the betting volume for all bets up to 200 dollars (equivalent to 97.4% of the total betting volume). The figure reveals that more than 37% of all bets are below \$20 while the

average individual bet is about \$35. There are more than 660 bets placed per race. This indicates that the pool of bettors is composed of many individuals who bet relatively small, yet not insignificant, amounts. Since these small bets are associated with considerable transaction costs, we conclude that a large majority of bettors in the alpine skiing market are non-professional individuals whose betting strategy might be influenced by changes in media coverage. This interpretation is in line with previous studies of sports market betting who have pointed out that most bettors participate for recreational fun (Lee et al., 2013).

Finally, it is worth mentioning that the average inverse odd for an athlete in our estimation sample is 0.18 and 0.12 for close victories and podium finishes, respectively. In both cases this probability is higher than the true average probability of an athlete winning the subsequent race (0.15 and 0.09, respectively). The difference illustrates the markup charged by the betting agency. The fact that betting odds do not sum up to one reflects that our data is in line with the literature on betting markets (Levitt, 2004).¹¹

3 The Identification Problem

3.1 Selection on Observables

The central research question of this paper is whether media attention affects betting market outcomes. A naive way to test this hypothesis is to run an ordinary least squares regression, assuming selection on observables. If we possessed all variables that affect outcomes, we could simply use our data set and fit the empirical model:

$$Y_{i,t+1} = \phi_i + \tau \text{TOP_RANK}_{i,t} + \mathbf{X}_{i,t} \phi + \varepsilon_{i,t}$$
(1)

where $Y_{i,t+1}$ denotes the outcome variable which can be media attention, performance, or

¹¹In a standard betting market model for a podium finish, the agency faces a classical monopolist problem with its markup given by $m = p_3 + p_4 - 1$ with p_3 and p_4 being the inverse odds for the 3rd and 4th athlete. Simulating the decision, we find that the agency optimally sets a mark-up larger than zero. Empirically, we can standardize the inverse odds for each race such that the sum of all probabilities is equal to one. The results we obtain are virtually identical to the estimates we show in Table 4. The point estimates (standard errors) for the estimation using average odds as the dependent variable are given by -0.026 (0.028) for the podium specification and by -0.011 (0.031) for the victory specification.

betting market outcomes of athlete i in race t + 1. Note that media attention is measured by the number of articles on the day after race t. The coefficient of interest, τ , indicates the impact of a top rank, either a victory or podium finish. Finally, $\mathbf{X}_{i,t}$ denotes a vector of athlete i's observed characteristics (gender, experience, prior successes, competitors), ϕ_i is an athlete-fixed effect, and $\varepsilon_{i,t}$ denotes the standard error clustered at the athlete level.

— Table 2 about here —

The results of estimating this model are shown in Table 2. We observe that top ranks (i.e., podium and victory) are positively correlated with media attention on the day after a competition. Moreover, the estimates show a negative relationship between high ranking positions and average odds. For the risk and performance measures, we find that a victory is associated with a higher probability to win the subsequent race. All these correlations are robust to the inclusion of several control variables as well as athlete-fixed effects. However, these results rely on the selection on observables assumption and should thus not be interpreted as causal effects.

3.2 Identification Strategy

The fundamental problem with estimating equation (1) is that ranking positions—including victories and podium finishes—are not randomly assigned across athletes. Although we can use a wealth of information to proxy for unobserved variables, including fixed effects to net out skill differences, we do not have information on, for example, injuries prior to the competition. In this section, we suggest a novel identification strategy to overcome this problem. The key idea of our approach is that in close races it is often a tiny margin that determines athletes' positions. If, for example, the time difference between two athletes ranked third and fourth is only a tenth of a second, we document that this can be attributed to random weather shocks. Hence, we can use those athletes that achieve a top rank (i.e., victory or podium finish) in a close race to estimate the causal effect on various outcomes. Throughout our analysis, we restrict the sample to races within season and discipline. This is necessary because times vary substantially across disciplines and seasons are separated by

more than half a year.¹² When limiting our sample to close races in which top ranks are arguably randomly assigned, we have to exclude most combined competitions and focus on slalom, giant-slalom, super-G, and downhill races.¹³

The focus of our analysis is on top ranking positions, namely victories and podium finishes. We motivate this by the fact that individual tournaments reward mainly athletes on the podium, and more specifically the winner of a race. This is reflected by FIS World Cup points, substantially higher prize money and increased media attention. In comparison with World Cup victories, however, podium finishes have a couple of advantages. First, we can draw on significantly more observations. Furthermore, when estimating the effect of a quasi-random victory, implicitly all observations in the control group finished on the podium. Hence, those athletes are also treated with a top rank, although the "treatment dose" is arguably lower. Thus, when using a victory as treatment, we only estimate the additional effect compared to a podium finish.

3.2.1 Random Top Ranks in Alpine Skiing

In contrast to other fields of sport, World Cup alpine skiing offers a unique feature that allows us to determine quasi-random top ranks. We illustrate this by a simple thought experiment. Assume there are only three variables that determine athlete i's final race time, $T_{i,t}$, in a given race t: the time-invariant skill of athlete i, denoted by θ_i , her training or fitness level, denoted by $\lambda_{i,t}$, and a noise parameter $n_{i,t}$ that captures all kinds of random shocks such as weather or snow conditions that can be heterogeneous or homogeneous across athletes.¹⁴ This setting allows us to write the time of athlete i in race j as a function of her skill and training levels as well as some random noise:

¹²Typically, the last race of a World Cup season is in March, while the first race of the next season takes place in October.

¹³In combined races, time differences are larger and there is a higher variance over time. This is mainly because combined races tend to be longer and have a smaller group of starters, which makes competition less fierce. Furthermore, there are only about five combined races per year as opposed to the other disciplines with about eleven.

¹⁴We assume skill to be persistent. However, we take into account that injuries may affect athletes' ability to exploit their skills by including the time-variant fitness parameter.

$$T_{i,t} = f(\theta_i, \lambda_{i,t}, n_{i,t}). \tag{2}$$

Moreover, her position in the final ranking, $P_{i,t}$, is a function of her own time as well as her competitors' times (all athletes k except i):

$$P_{i,t} = g(T_{i,t}, T_{k,t}) = g(\theta_i, \lambda_{i,t}, n_{i,t}, \theta_k, \lambda_{k,t}, n_{k,t}) \qquad \forall k \neq i$$
(3)

By means of this equation, we can illustrate why quasi-random top ranks are possible. Usually, skill differences explain most of the variation in ranking positions. This does not, however, imply that ranking positions are entirely driven by skill levels. Figure A.3 in the Appendix depicts a histogram of winners' and third-ranked athletes' ranking positions in the previous race. The fact that 40.3% of current winners and 22.6% of current third-ranked athletes achieved a podium in their past race documents positive serial correlation of our success measures. Yet the spread of the distribution reveals substantial variation in ranking positions. This challenges the idea that skill differences entirely determine ranking positions. In particular, if two athletes have almost identical race times, random fluctuations in the noise term become critical. Variations in $n_{i,t}$ can reduce athlete i's race time sufficiently to overcome skill and training deficits. In this way, a less skilled athlete can be lucky and draw a very low $n_{i,t}$ which enables her to achieve a better race time than a more skilled competitor.

For our estimation, the key identifying assumption is that the noise parameter $n_{i,t}$ has sufficiently large effects on individual race times in order to randomly assign relative ranking positions in close races. In skiing, the individual noise term, $n_{i,t}$, is comprised of several components. First, alpine skiing is an outdoor event and thus wind and weather conditions vary significantly over the course of a single race. Most notably changes in snow, wind, and sight alter individual prospects of success and can also lead to cancellation if race conditions are considered to be a serious risk for the athletes.¹⁵ Yet, the mere presence of unstable

¹⁵The following excerpt about the performance of U.S. competitor Bode Miller in 2009 illustrates the impact of wind. "Miller, a two-time overall World Cup winner, finished ninth Saturday as the Saslong downhill in Val Gardena, Italy, marked its 40th year. His performance was affected by a strong headwind that whipped up just as he and the other top contenders took the course", *New York Times*, December 20, 2009.

external conditions does not lead to cancellation and is broadly accepted as a natural source of variation among competitors. The impact of random wind, weather, and snow conditions is amplified by the fact that individual race times critically depend on the performance in key sections of the course. An error in these sections not only leads to an immediate time loss but also affects speed, and thus time, in the following sections.

It is crucial for our analysis to test whether there is any bunching of data around the thresholds which determine who wins a race or finishes on the podium. Following McCrary (2008) there should be a smooth distribution of observations around the cutoff. Otherwise there might be a distorting factor we need to address. Figure A.4 in the Appendix illustrates that the number of observations is in fact smooth at the cutoff for both treatments, victory and podium. This supports the assumption that athletes are not systematically located around the threshold.

3.2.2 Bandwidth Choice

What is a close race and what time difference can be considered random? An important identifying assumption of our research design is that treated and non-treated athletes are not systematically different with respect to pre-determined covariates. If finishing on the podium in a close race is driven by skills instead of luck, our approach would not allow us to assess the causal effects of quasi-random top ranks. To address this concern, we compare the characteristics of treated and non-treated athletes. We do this in two steps. First, by means of Figure A.5 in the Appendix, we show that athletes who win or finish on the podium are in general different from less successful athletes when comparing prior success. However, we find that there are no significant differences with respect to prior success when considering close races. This indicates that those who win or make it to the podium in a close race are not systematically more skilled. Once we restrict the sample to tournaments in which the time difference between successful and non-successful athletes, the running variable, is less than 0.15 seconds, the differences in pre-determined characteristics are insignificant. Note that we calculate the running variable as the time difference to the third-placed athlete for all athletes who did not finish on the podium and, equivalently, the time difference to the

athlete on the fourth position for all athletes on the podium.¹⁶ This leaves us with a negative running variable for athletes on the podium and a positive running variable for athletes who are not on the podium.

— Table 3 about here —

In Table 3, we compare athletes on the podium with those who missed it by up to fifteen hundredths of a second. There is no significant difference in any of the observable athlete characteristics. The top-ranked athletes in close races are not more experienced, successful, or risk-loving than their contestants in the control group. Moreover, we find no difference in their competition, media attention prior to the race, or betting market outcomes for the race which determines who is in the treatment and control group.¹⁷ Importantly, treated and non-treated athletes are also not different in terms of the probability of competing in the following races, which rules out the possibility that lower ranked athletes are discouraged from participating in subsequent races. However, it is important to note that treated and non-treated athletes obviously become systematically different if we extend the bandwidth. If we include athletes trailing the podium by a large time difference it is no longer plausible to consider the podium finish a result of 'luck'. Hence, we have to restrict the sample to observations with sufficiently small time differences in order to exploit 'random top ranks'. The decision to choose 0.15 seconds as the bandwidth for our estimations is the result of a trade-off: We can use more observations with a larger bandwidth but the allocation of ranking positions (and thus media attention) is only plausibly random for small bandwidths. As we show in Section 4.3, our specific choice of bandwidth does not affect the empirical findings.

3.2.3 Econometric Specification

For our estimation we assume that, except for the treatment, there is no reason why subsequent outcomes $(Y_{i,t+1})$ like media attention, performance, or betting odds should be a

¹⁶For the victory treatment, the running variable is the time difference to the winner for athletes who did not win and the time difference to the second-ranked athlete for all winners.

¹⁷Note that the balance tests remain unchanged when we include the running variable in the regression as documented in Table A.1 in the Appendix.

discontinuous function of the race time. We support this assumption using a large set of balance tests (cf. Tables 3, A.1, and Figure A.5). Hence, any discontinuity in the outcome variable at the cutoff level c_t is identified as the causal effect of the treatment. We estimate the treatment effect τ by fitting the linear regression

$$Y_{i,t+1} = \phi_i + \tau D_{i,t} + \beta (T_{i,t} - c_t) + \gamma [D \times (T_{i,t} - c_t)] + \mathbf{X}_{i,t} \delta + \varepsilon_{i,t}$$

$$\tag{4}$$

where ϕ_i is an athlete-fixed effect, $D_{i,t}$ indicates treatment (victory or podium), $[D \times (T_{i,t} - c_t)]$ allows for different slopes on each side of the cutoff, $\mathbf{X}_{i,t}$ is a vector of control variables, and $\varepsilon_{i,t}$ is the standard error term which we cluster at the athlete level.¹⁸ For the outcome variable, $Y_{i,t+1}$, we use media attention after race t, performance and risk-taking behavior in race t+1 as well as both betting odds and the number of bets in race t+1. Note that the inclusion of covariates could in principle improve the precision of the estimation (Frölich, 2007). We explored this possibility but did not find notable differences in the estimates. Moreover, squared and cubic terms of $(T_{i,t} - c_t)$ can be included to allow for a nonlinear relationship.¹⁹

4 Results

4.1 Effect on Media Attention

We first test whether media attention is affected by a top rank in a close race. Fitting the model specified in equation (4), we use the number of newspaper articles mentioning an athlete's name on the day and during the week after the race. All our regressions include athlete-fixed effects and thus use within-athlete variation. Hence, in the estimation we com-

 $^{^{18}}$ All control variables are not log-transformed to avoid losing about 18 percent of observations. The results are, however, not sensitive to this decision. The inclusion of athlete-fixed effects might be problematic in the sense that information is used for the estimation that was not available at time t. We thus re-ran the estimation with athlete-season-fixed effects and—in line with our main results—find a positive effect on media attention and no discontinuity in betting odds.

¹⁹The work by Hahn, Todd and van der Klaauw (2001) as well as Gelman and Imbens (2014) suggests to use local linear regression in an RD setting. In particular, high-order polynomials of the forcing variable should not be used. Thus, we omit squared and cubic terms of $(T_{i,t}-c_t)$ in our baseline regressions. However, the results are not sensitive to the specification.

pare the same athlete who achieves a high ranking position (i.e., victory or podium) in one race but not in the other. The great advantage of our data set is that we have enough observations to test whether the same person receives different levels of attention by the media if she performs only marginally better than her competitors.

— Table 4 about here —

Table 4 shows that those athletes who finish on the podium in a close race are mentioned about 31.5% (= 2.95/9.36) more often than those who barely miss the top three ranks. For a close victory we find an additional 15.4% increase.²⁰ Note that the point estimate for victory is considerably smaller than the estimate for a podium finish because most athletes in the control group also finished on the podium and thus benefited from increased media attention for top-ranked athletes. The positive impact of a high ranking position in close races is still present when counting all articles published during the seven days following the race as indicated in the second column in Table 4. By means of Figure 4, we can visualize the discontinuity in media attention around the cutoff time by plotting the average absolute media attention on the day after the competition.

— Figure 4 about here —

The difference in media attention between top-ranked and not top-ranked athletes is present even when considering only close races in which the time difference was tiny. These significant differences indicate that top ranks introduce a sharp discontinuity in absolute media attention. However, we also have to examine whether there are differences in relative media attention. Not only do athletes' sponsorship contracts depend on how many times they are mentioned compared to their competitors, it is also very likely that relative media attention affects bettors' expectation about who is going to win the next race. To test the effect on relative media attention, we define $m_{i,t}$ as athlete i's share of total media attention among all athletes within our preferred bandwidth of 0.15 seconds. For example, suppose

²⁰When restricting the sample to the period 2006–2014, we still find a large positive and significant effect of a close podium finish (and of a close victory) on media attention. The point estimates when using media attention on the day after the race are given by 4.75 and 3.66 for podium and victory, respectively.

racer A wins race t, racer B trails her by less than 0.15 seconds and all other athletes have a larger distance to the winner. Then we count all newspaper articles that mention racer A and we do the same for racer B. If the winner is mentioned in 60 articles and the second in 40 articles, we have $m_{A,t} = 0.6$ and $m_{B,t} = 0.4$, respectively. Formally, $m_{i,t} = A_{i,t} / \sum_{s} A_{s,t}$ with s containing all athletes who won race t (or achieved a podium finish) as well as all those missing the victory (or podium) by 15 hundredths of a second or less. Using this measure of relative media attention, we find a discontinuity of 11 percentage points at the threshold to the podium which corresponds to a 32% increase in media attention compared to the control group (see Table A.2 in the Appendix). The equivalent relative increase in media coverage for achieving a victory is 19%. Overall, these estimates strengthen the claim that top ranks causally affect media attention.

4.1.1 Media Attention Before and After a Race

Despite the fact that allocation to treatment in our case is arguably random for close victories and podium finishes, the question remains whether it is the very success that affects media attention. In order to investigate this, we compare the media attention of top ranked and lower ranked athletes at various points in time before and after the race.

In the balance tests shown in Table 3, we observe that before the race, successful and non-successful athletes receive very similar levels of attention by the media. This is not surprising, since treatment and control group seem to be balanced in terms of experience and prior success. However, after the race the control group—those who did not win the race or did not finish on the podium—receive significantly less media attention. Although all athletes in the treatment and control group show a very similar performance, media attention is tilted heavily in favor of those finishing on the top three positions of the ranking. A second observation is that, as expected, the difference in media attention is less pronounced when considering longer time periods. However, even when we examine all articles published in the week after a competition, we observe a significant gap between successful and non-successful athletes. This gap remains significant if we subtract articles published on the day after a race. In the long run, the gap in media attention subsides. This is shown in Table A.2 in

the Appendix and driven by the fact that within a month the next tournaments took place.

4.2 Effect on the Betting Market

When estimating the effect of media attention on betting markets it is important to first test whether the true probability of athletes to succeed is altered by achieving a top rank. If one-time great successes have an effect on performance, we also expect a difference in betting odds because bettors update their beliefs about the future performance of athletes based on the ranking positions. In this case, it would not be possible to disentangle the effect of higher media attention from the increased performance effect. However, if rankings have no effect on athletes' performance, the effect on betting odds is likely to depend on the discontinuity in media attention introduced by the ranking scheme.

4.2.1 Effect on the True Probability

To test whether athletes respond to what ranking position they achieve in one tournament, we investigate their risk-taking behavior and performance in the subsequent race. First of all, it is not surprising to find a substantial amount of serial correlation in our data set. The correlation between today's distance to the podium (victory) and the average position in the next race is $0.23 \ (0.14)^{21}$ The key question, however, is whether there is a discontinuity around the cutoff. We test this by plotting the average probability of achieving a victory in race t+1 around the time cutoff for a victory and podium finish in race t. The variable capturing whether an athlete wins the next race is our preferred measure of performance because it corresponds to the very event for which bettors can place bets.

The results shown in Figure 5 indicate that there is no discontinuity at the threshold. Neither a victory nor a podium finish in a close race has a causal effect on the probability of winning the next race. One may argue that this finding is driven by the choice of the dependent variable. Very few athletes win a race in their careers and thus victory might be

²¹Figure A.6 in the Appendix provides a graphical illustration of this positive serial correlation of performance.

an imprecise measure of performance. To test whether the results are sensitive to the choice of the dependent variable, we use several alternative measures of performance including the probability of a podium finish and the average position in the next race. The results in Table A.2 in the Appendix confirm that professional ski athletes do not change their performance following a top position in the ranking.

We also investigate whether achieving a high ranking position in one tournament changes the risk-taking behavior of athletes in subsequent races.²² If rankings affect risk-taking, the interpretation of the performance result above would be more difficult to interpret because rankings would alter the composition of athletes who obtain a final race time and thus a performance measure. In the context of our study, it may be expected that athletes change their behavior and perception of risk after a quasi-random top rank. Athletes may misinterpret one-time victories as signals of high ability. As a consequence, they might act too ambitiously in subsequent races, leading to an increase in the probability of crashes. Hoelzl and Rustichini (2005), for example, find in an experiment that overconfidence becomes important when monetary payments are at stake. Yet our results indicate that athletes on a top ranking position are not more likely to finish the subsequent race. In addition, their position and the probability of finishing on the podium in the next race do not differ from those athletes who missed the top ranks (i.e., victory or podium) by a small margin. From an econometric point of view, this finding supports our estimation of the effect on performance without taking into account an attrition bias by using a principal stratification framework (Frangakis and Rubin, 2002).²³ Finally, we consider the overall time in race t+1as a plausible outcome variable.²⁴ Again we find no difference between successful and nonsuccessful athletes. The regression results reported in Columns (3) and (4) of Table 4 confirm that the point estimates of top ranks on risk-taking and performance are very close to zero

²²Föllmi, Legge and Schmid (2016) investigate risk-taking in alpine skiing and document that athletes react to small changes in the perceived time difference to the leader by changing their risk strategy between two runs in the disciplines slalom and giant slalom.

²³Consider, for example, the case in which a one-time success had a negative effect on the survival probability. This would indicate increased risk-taking among successful (i.e., treated) athletes. We discuss this concern in detail in the Appendix B.

 $^{^{24}}$ In contrast to using ranking positions in race t+1, the advantage of the race time is that we do not have to address the problem of potentially violating the stable unit treatment value assumption (SUTVA) which is necessary for the estimation of causal effects. In Appendix C we provide a detailed discussion.

and far from being statistically significant.

Before turning to the impact of top ranking positions on the betting market we briefly summarize our key findings. Whether an athlete wins or finishes on the podium in a close race has a substantial effect on the amount of media attention she receives. However, it does not affect her risk strategy and performance in the next race. Hence, if betting odds reflect true probabilities there should not be any significant difference between top ranked and lower ranked athletes.

4.2.2 Effect on the Betting Market

Given the large positive effect of top ranking positions on media attention, it appears likely that public expectations about the performance of top-ranked athletes in the next race increase. A natural way to test whether public expectations discontinuously rise as a consequence of an exogenous shift in media attention is the analysis of betting data. Information on betting behavior should reflect prior expectations of bettors in an incentive-compatible way because a betting agency that deviates from bettors' expectations would either incur losses (if betting odds are too high) or attract no bets (if odds are too low). We use betting odds from Betfair, the world's largest Internet betting exchange, for the period of 2006–2014 to explore the impact of top ranks in close races on betting market outcomes.

The distribution of betting odds across ranking positions is shown in Panel (b) of Figure 1. We observe a negative gradient with better ranked athletes facing higher inverse odds in the next race. There is also a pronounced difference for close winners and non-winners as well as between podium and non-podium finishers. However, we want to examine whether an athlete who randomly achieved a top rank faces different odds in the subsequent race. Fitting the empirical model of equation (4) with betting odds and the number of bets as dependent variables, we obtain the results reported in columns (5) and (6) in Table 4. For both outcomes, the estimates are very close to zero and fall short of conventional significance levels. These results are consistent with a graphical inspection provided by Figure 6.

— Figure 6 about here —

Based on these findings there are two conclusions. First, athletes who achieve a top rank-

ing position in a close race receive higher subsequent media attention but not a significantly higher number of bets. The results remain unchanged if we use the volume of bets instead of using the total number of bets. The second conclusion from our estimation is that the absence of any discontinuity in betting odds matches the fact that randomly assigned higher ranking positions do not increase the true probability of winning the next race. In this sense, columns (5) and (6) of Table 4 support the idea of using markets for predictions (Wolfers and Zitzewitz, 2006).

4.2.3 Betting Market Efficiency

We use our data set and investigate in more detail to what extent betting odds reflect true probabilities. In panel (a) of Figure 7, we show the estimated effect of finishing on the podium on the true probability of achieving a victory in the next race. The estimation is conducted for all bandwidths between 0.05 and 4.00 seconds.

We observe that once we include athletes trailing the podium by more than a full second, those who finished on the podium are significantly more likely to win the subsequent race. Interestingly, panel (b) shows that there is also a significant difference in (inverse) betting odds between athletes on the podium and other athletes once the bandwidth is larger than one second. These results suggest that the betting market mimics true probabilities of future events.

4.3 Robustness Checks and External Validity

In this subsection, we discuss the robustness of our main results. In a first step, we investigate whether top ranks have an effect on betting odds at specific points in time of the betting process. Second, we discuss the bandwidth choice in our regression discontinuity design. Third, we explore whether we obtain the same results in an instrumental variables framework using betting market behavior as outcomes, media attention as treatment, and top ranking positions as instrument. Finally, we address concerns about our source of media data, market liquidity, and selective participation.

4.3.1 Initial, Average, Final Odds

To shed light on the betting agency's behavior and the bettors' corresponding response, we analyze initial and final betting odds. First, it might be that the estimated effect on the average odd is driven by differences in the initial odds which are exclusively determined by the betting agency. These odds change over time until the next race starts. The changes in odds are driven by new information (e.g., news about an athlete being handicapped) as well as the number of bets placed. If more and more bettors want to buy bets that athlete i will win the next race, her odds are likely to decrease. We have data not only on the initial odd but on all odds that were offered for a given individual and race. Hence we can separate the initial odd, the average odd and the final odd. This wealth of information helps us understand whether the betting agency attempts to increase its profit by offering lower odds as a result of higher media attention. We can also investigate whether such a strategy is successful or whether the market adjusts the price. Table A.2 in the Appendix shows that the betting agency offers 'fair' odds in the first place. The point estimates for the average and final odds are very similar to those we obtain using the initial odds. This finding supports the idea that bettors' expectations are not biased as a result of selective media attention.

4.3.2 Bandwidth Choice

Throughout our empirical analysis we use the concept of random top ranks to identify the causal effects of media attention. As we explained in Section 3, it is crucial to focus on close races to overcome the identification problem. A central question in this regard is what time difference between two athletes can be attributed to random shocks. This means that it remains a priori unclear what bandwidth we should use in our estimations. In all regressions so far we have used a bandwidth of 15 hundredths of a second. The bandwidth choice was primarily based on the results of the balance tests in Table 3 as well as on the comparison of prior success for top-ranked and other athletes depicted in Figure A.5 in the Appendix. We can illustrate the magnitude of 0.15 seconds by plotting the distribution of time differences to the podium. Figure A.7 in the Appendix shows the distribution as well as a vertical line for the bandwidth we use in our estimation. When restricting the sample to those athletes

trailing the podium by 0.15 seconds or less, only 10% of the sample are included.

In order to investigate the robustness of our empirical results, we re-run the RDD estimation (equation 4) using different bandwidths ranging from 0.10 to 0.50 seconds. In our preferred specification we include athlete-fixed effects to hold constant all individual-specific covariates. Figure A.8 in the Appendix depicts the effect of a podium finish on media attention, performance, and betting odds using different bandwidths. There are two notable observations. First, the point estimate is very stable irrespective of the bandwidth choice. Second, when decreasing the sample size the confidence intervals become very large. Using a bandwidth of 0.10 seconds, for example, leaves us with only 304 observations in the betting odds estimation that includes athlete-fixed effects. Our preferred bandwidth of 0.15 seconds is the result of the trade-off between bias and precision: On the one hand, we can use more observations with a larger bandwidth. On the other hand, the allocation of ranking positions (and thus media attention) is only plausibly randomized for small bandwidths.

4.3.3 Instrumental Variable Estimation

Thus far we have analyzed the effects of media attention on the betting market using separate regressions that relate randomized top ranks to media and betting outcomes. While top ranks create sizable discontinuities in media attention, the results of the intention-to-treat (or reduced form) regression suggest that top ranks do not create a difference in betting odds. This indicates that the effect of interest, the parameter on media attention in the second-stage regression with betting market outcomes as dependent variable, is absent (Angrist and Krueger, 2001). To explore this (absent) effect in more detail, we estimate a two-stage least-squares regression using our betting market variables as outcomes, media attention as treatment, and top ranks as instrument. We focus on close podium finishes and extend the bandwidth to half a second to avoid suffering from weak instrument problems.

— Table 5 about here —

Table 5 reports the results of these regressions using the average inverse odds as well as the total number of bets in the subsequent race as dependent variables. All regressions include the distance to the podium as well as athlete-fixed effects. The estimates highlight that the

effect of the media on betting market outcomes is very close to zero and not significant.

These findings add to the previous results using reduced form regressions suggesting that
there is no effect of media attention on betting behavior.

4.3.4 Media Data from NewsLibrary

In order to examine the robustness of our empirical findings about the effect of rankings on media attention, we address the fact that our source of media data (Swissdox) is a Swissbased, largely unknown source. An alternative source is the American newspaper archive NewsLibrary. For all top-15 athletes in all races between 1992 and 2014 we use NewsLibrary and count the number of articles mentioning the athletes' names. As before, we count the articles before and after the race over different time periods. We obtain a distribution of media attention across ranks that is very similar to the one that we observed for the Swissdox data. There is a notable gap between the winner and the runner-up as shown in Figure A.1 in the Appendix. Even more noticeable is the difference between the amount of media attention received by the third-ranked athlete compared to those athletes who missed the podium. We can use the data from NewsLibrary to repeat the OLS and RDD estimation. The estimates are very similar to the ones we obtained when comparing athletes around the podium cutoff as we document in the Appendix Figure A.9.

4.3.5 Media Attention versus Ranking Lists

Given that both Swissdox and NewsLibrary also contain ranking lists, one could argue that we do not find an effect of media attention on betting markets simply because our data is a weak proxy for true media attention. We address this potential issue by an additional scraping procedure which eliminates all ranking lists from our sample.²⁵ Note that this is a conservative approach as it removes all ranking lists but also some additional articles which makes it more challenging to obtain significant effects in the first stage regressions.

Estimates shown in Table A.3 of the Appendix indicate that a close podium finish or victory has a positive and significant effect on media attention after a race. Compared to

²⁵Technically, we again search for an athlete's name during various periods around the race date. However, we leave out all articles that contain ranking positions such as "7." or "8." which every ranking list includes.

our main results, we find that the relative impact of success on media attention is even larger if we exclude ranking lists.

4.3.6 Liquidity of the Betting Market

One potential concern about the interpretation of our results is that the alpine skiing betting market is very thin or illiquid. This might be worrisome for two reasons. First, in a very illiquid market betting agencies might not adjust their odds in response to participants' beliefs. If only few individuals participate, betting agencies may anticipate that there is very little dynamic in the market and consequently do not take into account bettors' beliefs but rather charge a fixed mark-up. As a result, the finding that media attention has no effect on betting odds stems from the supply (betting agencies) and not—as we suggest in this paper—from the demand side (bettors). Second, in very illiquid markets it might not be profitable to adjust odds as a response to bettors' beliefs because the betting volume is simply to small. Moreover, the predictive power of betting markets might be limited in the absence of liquidity because information is not efficiently and timely aggregated if only few individuals participate.

To address this concern, we explored several aspects of the betting data. First, even though the average individual bet is only about \$35, the total volume per race is \$23,313 and the average number of bets is 660. Furthermore, betting odds change substantially over time. For more than 99.7% of all bets there is at least one change of odds. The average number of changes is eight. In addition, these changes are substantial: the standard deviation of inverse odds is 0.07 which is about a quarter of the overall mean of 0.27. Second, we probe whether our main result that media attention has no effect on betting odds also holds in a very liquid market. To do so, we split our sample by two measures of market liquidity, namely the total volume and the number of bets per race. As indicated in Table A.4 in the Appendix, we find no effect of media coverage on betting odds in less liquid but also in highly liquid markets.

These results are in line with the literature that investigates the efficiency properties of betting markets. Several studies have explored whether prediction markets can be manipulated.²⁶ Camerer (1998) finds that placing temporary bets in order to manipulate horse race markets is unlikely to affect odds in the long term. Similarly, Rhode and Strumpf (2004, 2008) examine various prediction markets and conclude that these markets cannot be systematically manipulated beyond short time periods. Finally, Hanson, Oprea and Porter (2006) as well as Oprea et al. (2008) provide experimental evidence that a group of traders cannot manipulate the accuracy of forecasts. The only exception to this literature is a study by Rothschild and Sethi (2015) which finds some evidence of possible manipulation in the 2012 Intrade presidential prediction market.

4.3.7 Selective Participation

Another important potential concern is that athletes who finished on the podium might participate in different races than athletes who barely missed the podium. In particular, it might be that those athletes on the podium compete in more races with fiercer competition. To explore this concern, we first present institutional evidence on participation in FIS races and then explicitly test whether athletes selectively participate in World Cup races. In general, participation in the FIS World Cup series is reserved to the best athletes in a certain discipline. Less experienced and less successful athletes are competing in the FIS European Cup and the Continental Cup. In all three series, athletes can win FIS points that allow participation in the World Cup which is the most prestigious series in terms of prize money and media attention. Yet, most athletes in our sample have a high score of FIS points and thus a fixed starting position in the World Cup. Hence, the additional World Cup points from a close podium finish or a close victory should not affect eligibility for the next race. Furthermore, it is important to note that organizers have no power to select the competing athletes except that they can give wild cards to certain athletes who would not be classified (mostly to young local athletes). There might, however, be selective participation due to injuries or strategic reasons.

To explore the effect of a random victory and podium finish on participation due to injuries or strategic reasons, we reran the main estimations using participation as an outcome.

²⁶Meng (2016) provides a discussion of how the illiquidity of a prediction market might be a serious concern.

As indicated by the first two columns of Table A.5 in the Appendix, the point estimates are close to zero and not significant. We also examined whether athletes select themselves into races with stiffer competition by regressing the total sum of victories among top 5 athletes in the next race on our treatment indicators, victory and podium. Columns (3) and (4) of Table A.5 in the Appendix report that there is no significant difference.²⁷ To explore whether athletes select into races with higher prize money, we split the sample for which we have data on prize money into races with above- and below-median total prizes. Again, we find no evidence that previously successful athletes select into races with more prize money. Overall, these results suggest that future participation decisions are not driven by today's ranking positions and thus the sample of racers just above and below the podium cutoff is not selective.

5 Conclusion

This paper investigates how media attention affects betting markets. In a first step, we use a novel data set on all World Cup tournaments in alpine skiing between 1992 and 2014 to show that media attention is highly skewed in favor of successful athletes. Even if performance differences are tiny, there is a significant gap in media attention between athletes on the podium and those athletes who miss it. We exploit this discontinuity in media attention to estimate the causal effect on betting market outcomes.

Our results reveal that ranking positions significantly affect the amount of media attention individuals receive after a tournament. Although prior theoretical and empirical work suggests that top ranks increase athletes' self-confidence and goal-setting behavior, we find no effect of high ranking positions on subsequent performance or risk-taking behavior. Since the true probability of winning the next tournament is not affected by a top rank in a close race, we expect to find no difference in betting odds for athletes with different amounts of media attention if the betting market is efficient. Using data from Betfair, we find that increased media attention has neither an effect on average odds nor on the number of bets.

²⁷Note that these results are robust to using alternative measures of competition in the next race (e.g., number of podiums among top 5 and top 10 athletes).

The betting agency offers initial odds that reflect the unchanged true probability of athletes succeeding in the subsequent tournament. While Thaler and Ziemba (1988) suggest that bettors can achieve a positive rate of return by placing bets on extreme favorites, we find no such opportunity. Our results suggest, in contrast to Levitt (2004), that bookmakers do not gain from being more proficient at predicting future events than bettors.

Our findings with respect to the distribution of media attention are consistent with theoretical studies on markets for attention (Falkinger, 2007, 2008). In an information-rich world, media have to concentrate information and sport athletes compete for the scarce resource of media attention. Since athletes in World Cup tournaments draw a large share of their earnings from sponsorship contracts, being among the top-3 is of particular importance to get higher media attention which translates into better sponsorship deals.

Overall, our findings add to the growing literature on the economic impact of the media (DellaVigna and La Ferrara, 2015). We show that media attention is highly biased in favor of successful individuals but this bias neither affects prices nor quantities in the betting market. While our empirical approach adds credible causal evidence on the effects of the media using field data, exploring the relationship between attention and expectations about future events in different settings or in a lab environment appears to be a fruitful area for future research.

Tables and Figures

Table 1: Descriptive Statistics

Variable	Mean	Std. Dev.	Min.	Max.	N
I. World Cup Alpine Skiing:					
Position	7.96	4.32	1	15	23,761
Victory	0.07	0.25	0	1	23,761
Podium	0.20	0.40	0	1	23,761
Time Distance to Victory	148.73	140.34	0	3,705	23,761
Time Distance to Podium	71.40	107.45	-968	3,220	23,761
Male	0.51	0.50	0	1	23,761
Age	26.42	3.67	16.38	41.68	23,761
Experience (# Races)	101.29	80.02	1	443	23,761
# Victories at Time of Race	3.99	7.62	0	59	23,761
# Podiums at Time of Race	11.18	17.40	0	109	23,761
Finished Next Race	0.82	0.39	0	1	19,430
Position in Next Race	11.66	9.25	1	65	$15,\!845$
Time in Next Race	$11,\!199.10$	$2,\!675.59$	5,307	$25,\!529$	$15,\!845$
II. Media Attention:					
Articles the Day after a Race	6.62	10.38	0	125	23,761
Articles the Week after a Race	15.07	25.61	0	381	23,761
Articles the Month after a Race	45.65	82.17	0	974	23,761
III. Betting Market:					
Initial Odds in Next Race	17.15	17.52	1.07	200	2,840
Final Odds in Next Race	17.72	25.42	1.30	1,000	2,840
Average Odds in Next Race	17.33	17.45	1.31	200	2,840
Inverse initial Odds in Next Race	0.13	0.12	0	0.93	2,840
Inverse final Odds in Next Race	0.12	0.12	0	0.77	2,840
Inverse average Odds in Next Race	0.12	0.11	0	0.76	2,840
Volume of a Bet in Next Race (in Dollars)	378.25	861.53	0.06	$10,\!290.18$	2,840
Number of Bets in Next Race	12.18	15.18	2	213	2,840

Note: The table presents descriptive statistics for all variables used in the empirical analysis. Panel (I) presents information on the Alpine skiing data set. Time is always measured in hundredths of a second. Data on media attention in Panel (II) is drawn from our Swissdox database covering all athletes with a final rank between 1 and 15. Panel (III) is based on Betfair. Note that one bet observation is defined as a bet on a specific event ("athlete A wins race X") with a specific odd. Hence the number of bets is the total of all individual bets for a specific event. The volume of bets is also defined at the bet observation level. The time period is 1992–2014 for the World Cup and media data and 2006–2014 for the betting data.

Table 2: Ordinary Least Squares Regression

	Media Attention		Performance		Betting Market

Note: The table shows the results of twelve separate linear regressions using six different dependent variables as indicated in the top rows. The data on media attention is taken from Swissdox. Media attention is measured by the number of articles published on the day and during the week after the race t. In columns 3 and 4, the dependent variable is the probability of finishing (col 3) or achieving a victory (col 4) in race t+1. In the last two columns, log inverse average odds as well as the log of the total number of bets for the race t+1 are used as dependent variable. The sample includes all athletes who finished in the top-5 in race t. Columns (1) to (4) include tournaments from 1992-2014 while columns (5) and (6) are based on 2006-2014. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by **, and at the 1% level by ***.

Table 3: Balance Tests for Close Podium Finish

	Mean V			
	Treatment	Control	Difference	p-value
A: Athlete Characteristics				
Male	0.55	0.56	-0.00	0.98
Experience	114.80	117.50	-2.70	0.48
Average Survival	0.93	0.93	-0.00	0.89
Survival in Last Race	0.86	0.87	-0.01	0.64
Number of Victories	5.63	5.53	0.10	0.76
Number of Podiums	15.58	15.33	0.25	0.76
First Prize Possible	0.60	0.59	0.01	0.50
B: Competition				
Total Podiums among Top 5	76.49	76.72	-0.22	0.92
Total Victories among Top 5	31.33	31.40	-0.07	0.93
Total Podiums among Top 10	135.18	135.38	-0.19	0.95
C: Media Attention				
Day Before Race t	5.79	5.34	0.45	0.23
Week Before Race t	15.26	14.74	0.51	0.60
Month Before Race t	49.69	48.76	0.93	0.78
D: Betting Market				
Average Odd Race t Volume in Race t	13.25 378.34	14.03 388.55	-0.78 -10.21	0.50 0.90

Note: The table shows mean comparisons (t-tests) for all relevant pre-treatment variables. The sample includes all athletes within a bandwidth of 0.15 seconds around the podium. Experience is measured by the total number of races prior to the race, survival in last race is the indicator for successfully finishing in the preceding race, victory and podium measure the total number of an athlete's victories and podiums prior to the race. Media attention is measured by the total number of articles mentioning an athlete's name in the Swissdox archive. The sample in A–C includes tournaments from 1992-2014 while part D is based on 2006-2014.

Table 4: Regression Discontinuity for Random Top Ranking Positions

	Media Attention		Performance		Betting Market	
Mean of dep. var.:	Day After 9.36	Week After 20.83	Survival 0.85	Victory 0.09	Inv. Odds 0.12	# Bets 1.96

Observations R-squared	$916 \\ 0.255$	916 0.197	811 0.029	811 0.005	$ \begin{array}{c} 221 \\ 0.227 \end{array} $	$ \begin{array}{c} 221 \\ 0.074 \end{array} $

Note: The table shows the results of twelve separate linear regressions using six different dependent variables as indicated in the top row. In Part (I) the treatment variable is a podium finish while in part (II) treatment is defined by victory. The sample includes all athletes within a bandwidth of 15 hundredths of a second and to athletes finishing first or second in Part II. The data on media attention is taken from Swissdox. In the last two columns, inverse average odds as well as the log of the total number of bets for the race t+1 are used as dependent variable. Columns (1) to (4) include tournaments from 1992-2014 while columns (5) and (6) are based on 2006-2014. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by **, and at the 1% level by ***.

Table 5: Instrumental Variable Estimation

	Inv. Odds		# I	Bets
Mean of dep. var.:	0.12	0.12	1.95	1.95
Log Media Attention	0.0015 (0.0013)	0.0015 (0.0012)	-0.0202 (0.0165)	-0.0175 (0.0146)
Fixed Effects Covariates Instrument	Athlete No Podium	Athlete Yes Podium	Athlete No Podium	Athlete Yes Podium
Observations F-value	1,356 8.64	1,356 10.56	1,356 8.64	1,356 10.56

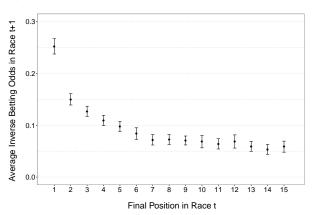

Note: The table shows the results of four separate linear regressions using two different dependent variables as indicated in the top row. The sample includes all athletes within a bandwidth of 50 hundredths of a second. The data on media attention is taken from Swissdox. The dependent variables are log inverse average odds as well as the log of the total number of bets for the race t+1. All columns include tournaments from 2006-2014. The F-value is based on the Kleibergen and Paap (2006) rk Wald F statistic. The values of the Cragg and Donald (1993) F statistic are given by 21.00 and 26.16 for the specification without and with control variables. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by **, and at the 1% level by ***.

Figure 1: Media Attention and Betting Odds for each Ranking Position

(a) Articles on the Day after Race t

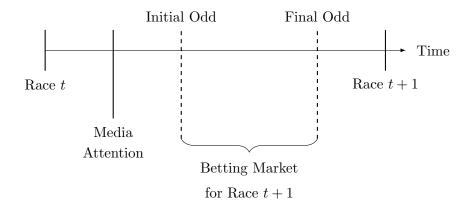

(b) Average Betting Odds in Race t+1

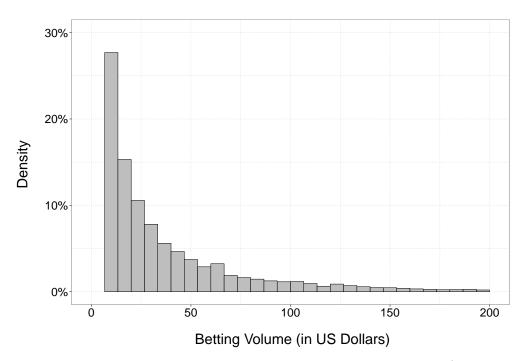

Note: The figure in Panel (a) shows the average number of articles that mention an athlete who finished on a specific position in race t. Media attention is measured on the day after the race took place. In Panel (b), we show the average of all inverse betting odds for bets offered before the race t+1 took place for each ranking position in race t. The bars indicate 95% confidence intervals.

Figure 2: Illustration of the Timing of Events

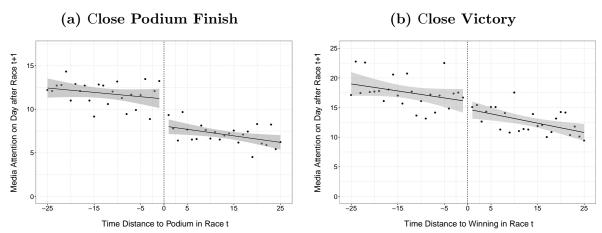

Note: The figure illustrates the timing of events. After race t, the betting market for the next race opens with an initial odd for each athlete. We measure media attention on the day after race t took place. The betting market closes with a final odd before race t+1 takes place.

Figure 3: Distribution of Betting Volumes

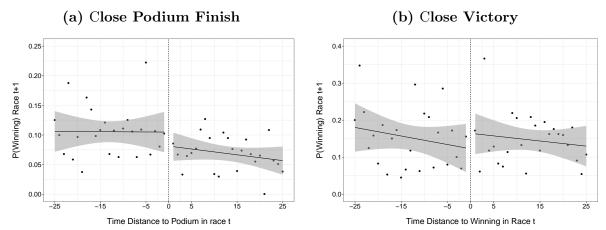

Note: The figure shows the distribution of the volume of each individual bet (in US Dollars). Note that we drop all observations greater than \$200 that account for 3.6% of total observations.

Figure 4: Effect of Top Rank on Media Attention

Note: The figures show a linear fit for the number of media articles that mention an athlete (on the day after a race took place) for both treatment (left) and control group (right). In panel (a) we compare victory and non-victory while in panel (b) athletes on the podium are compared with those missing it by 25 hundredths of a second or less. Both variables on the x-axis are expressed in units of hundredths of a second. The grey region indicates the 95% confidence interval.

Figure 5: Effect of Top Rank on Performance

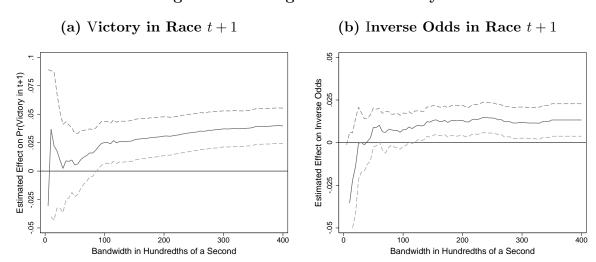

Note: The figures show a linear fit for the probability of achieving a victory in the subsequent race for both treatment (left) and control group (right). In panel (a) we compare victory and non-victory while in panel (b) athletes on the podium are compared with those missing it by 25 hundredths of a second or less. Both variables on the x-axis are expressed in units of hundredths of a second. The grey region indicates the 95% confidence interval.

Figure 6: Effect of Top Rank on the Betting Market

(a) Close Podium Finish (b) Close Victory (c) Close Victory (b) Close Victory (c) Close Victory (d) Close Victory (e) Close Victory (f) Close Victory (g) Clo

Note: The figures show a linear fit for the average inverse betting odds in the next race for both treatment (left) and control group (right). In panel (a) we compare victory and non-victory while in panel (b) athletes on the podium are compared with those missing it by 25 hundredths of a second or less. Both variables on the x-axis are expressed in units of hundredths of a second. The grey region indicates the 95% confidence interval.

Figure 7: Betting Market Efficiency

Note: The figures show the estimated effect of a close podium finish on the probability of winning the subsequent race (Panel a) as well the inverse average odds in the subsequent race (Panel b). Both variables on the x-axis are expressed in units of hundredths of a second. The dashed lines indicate 95% confidence intervals.

Appendix (For Online Publication)

Appendix A: Additional Tables and Figures

Table A.1: Balance Tests for Close Podium Finish Controlling for Distance to Podium

	Mean V			
	Treatment	Control	Difference	p-value
A: Athlete Characteristics				
Male	0.55	0.56	0.00	0.28
Experience	114.80	117.50	-2.70	0.48
Average Survival	0.93	0.93	0.00	0.87
Survival in Last Race	0.86	0.87	-0.01	0.77
Number of Victories	5.63	5.53	0.10	0.10
Number of Podiums	15.58	15.33	0.25	0.15
First Prize Possible	0.60	0.59	0.01	0.60
B: Competition				
Total Podiums among Top 5	76.49	76.72	-0.22	0.94
Total Victories among Top 5	31.33	31.40	-0.07	0.92
Total Podiums among Top 10	135.18	135.38	-0.19	0.87
C: Media Attention				
Day Before Race t	5.79	5.34	0.45	0.89
Week Before Race t	15.26	14.74	0.51	0.88
Month Before Race t	49.69	48.76	0.93	0.75
D: Betting Market				
Average Odd Race t Volume in Race t	13.25 378.34	14.03 388.55	-0.78 -10.21	$0.45 \\ 0.77$

Note: The table shows the mean for all relevant pre-treatment variables for treatment and control group as well as the difference. The p-value comes from a regression of the pre-treatment variable on podium controlling for the assignment variable (distance to podium). The sample includes all athletes within a bandwidth of 0.15 seconds around the podium. Experience is measured by the total number of races prior to the race, survival in last race is the indicator for successfully finishing in the preceding race, victory and podium measure the total number of an athlete's victories and podiums prior to the race. Media attention is measured by the total number of articles mentioning an athlete's name in the Swissdox archive. The sample in A–C includes tournaments from 1992-2014 while part D is based on 2006-2014.

Note: The table shows the results of twelve separate estimations using six different dependent variables as indicated in the top row. We use the inverse of both initial and final odds in columns (5) and (6). In Part (I) the treatment variable is a podium finish while in part (II) treatment is defined by victory. The sample includes all athletes within a bandwidth of 15 hundredths of a second. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by **, and at the 1% level by ***.

Table A.3: Media Attention without Lists

	Day After (1)	Week After (2)	Day After (3)	Week After (4)
Mean of dep. var.:	4.84	11.02	8.02	17.58

	(0.027)	(0.090)	(0.045)	(0.091)
Competition	-0.000	0.006	0.009*	0.026**
	(0.003)	(0.006)	(0.005)	(0.012)
Observations	2,209	2,209	907	907
R-squared	0.138	0.133	0.202	0.178

Note: The table shows the results of four separate linear regressions using media attention on the day or week after a race as dependent variable. We exclude those articles from media attention that (likely) reflect mere ranking lists. In columns (1) and (2), the treatment variable is a close podium finish while in the last two columns, treatment is defined as winning a close race. The sample includes all athletes within a bandwidth of 15 hundredths of a second. Control variables include experience, gender, prior success, and competition. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by **, and at the 1% level by ***.

Table A.4: Effect on Betting Market by Liquidity

	Dependent variable: avg. odds						
Liquidity Measure	Vol	ume	Nun	nber

	(0.000)	(0.000)	(0.000)	(0.000)		
Observations	115	106	107	114		
R-squared	0.445	0.506	0.557	0.376		

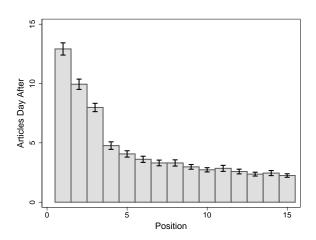

Note: The table shows the results of eight separate linear regressions using average odds as dependent variable split by two measures of market liquidity, namely the total volume and the number of bets. The first column uses only data on races with a total betting volume lower than the median; the second column uses races with above-median volumes. The third column uses data on races with a below-median number of bets; the fourth column uses races with an above-median number bets. In Part (I) the treatment variable is a podium finish while in part (II) treatment is defined by victory. The sample is restricted to all athletes within a bandwidth of 15 hundredths of a second. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by ***, and at the 1% level by ***.

Fixed Effects		Athlete		Athlete		Athlete
Observations	811	811	688	688	93	93
R-squared	0.024	0.028	0.707	0.610	0.181	0.098

Note: The table shows the results of twelve separate linear regressions. Columns (1) and (2) use a binary indicator that captures whether an athlete participated in the subsequent race as dependent variable. Columns (3) and (4) use a measure of competition in the next race as dependent variable, namely the total number of victories among top 5 athletes. Columns (5) and (6) use a dummy variable that captures whether an athlete's next race prize money was above the median prize money. In Part (I) the treatment variable is a podium finish while in part (II) treatment is defined by victory. The sample is restricted to all athletes within a bandwidth of 15 hundredths of a second. Note that the number of observations for columns (3) and (4) are lower because competition in the next race is only defined for athletes who participated in this race. In addition, the number of observation for the prize money estimations in columns (5) and (6) is lower as we have only data on prize money for about 17% of all completed races. Numbers in brackets indicate standard errors clustered at the athlete level. Significance at the 10% level is represented by *, at the 5% level by ***, and at the 1% level by ***.

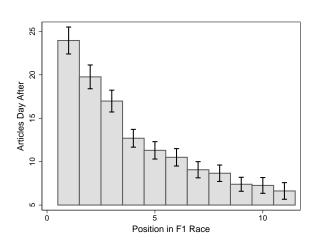

Figure A.1: Distribution of NewsLibrary Media Attention

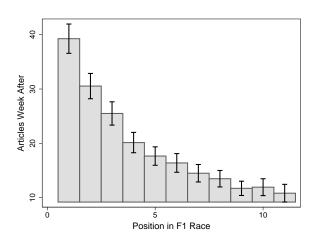

Note: The figure shows the distribution of media attention across the ranking positions in World Cup Alpine Skiing between 1992–2014. The data is based on NewsLibrary. On the left-hand side, we show media attention on the day after a race while on the right-hand side, we show the number of articles published in the week after the race. Whiskers indicate 95% confidence intervals.

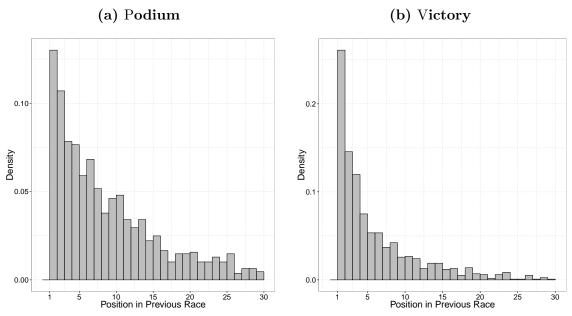

Figure A.2: Distribution of Media Attention in Formula One

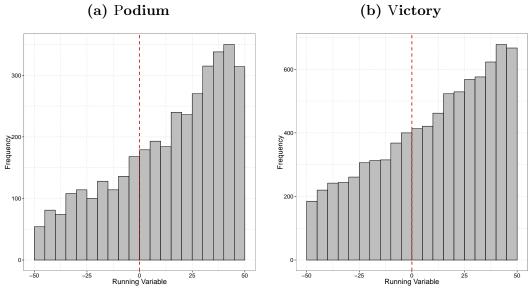

Note: The figure shows the distribution of media attention across the ranking positions in Formula 1 races between 1992–2014. The data on media attention is based on Swissdox. On the left-hand side, we show media attention on the day after a race while on the right-hand side, we show the number of articles published in the week after the race. Whiskers indicate 95% confidence intervals.

Figure A.3: Previous Positions of Winners and Third-Ranked Athletes

Note: The figures show histograms of the ranking positions in the previous race (t-1) of third-ranked athletes and winners in the current race (t).

Figure A.4: Observations around the Cutoff

Note: The histograms show the densities of race times around the cutoff for a podium and victory finish. Both running variables are expressed in units of hundredths of a second. In line with McCrary (2008), this indicates that there is no manipulation around the respective cutoffs. In panel (a) we plot the distance to rank 2 (from left-hand side) and 1 (from right-hand side), respectively. For the distance to the podium in panel (b), we plot the distance to rank 4 and 3, respectively.

Figure A.5: Balance Tests by Bandwidth

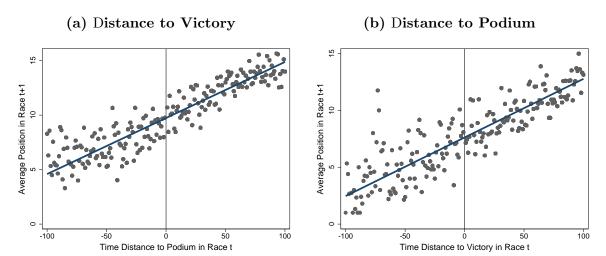

(a) Prior Success by Podium (b) Prior Success by Victory

Note: The figures show the results of t-tests on athletes' number of podium finishes prior to the race determining treatment. In plot (a), treatment is defined by podium while in plot (b) it is based on whether an athlete finished as the winner. The sample includes all tournaments between 1992-2014. Confidence intervals at 95% are shown.

Bandwidth (in 0.01 sec

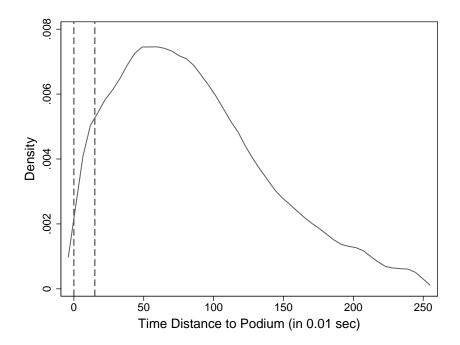

Bandwidth (in 0.01 sec

Figure A.6: Serial Correlation in Individual Performance

Note: The figure shows the average position in race t+1 for each distance to the winner (left-hand side) or podium (right-hand side) in race t. In addition, we add a linear regression line. The sample includes all athletes between 1992–2014 who finished within a bandwidth of one second to the victory (a) or podium (b).

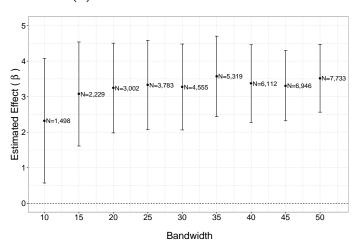

Figure A.7: Distribution of Running Variable and Bandwidth Choice

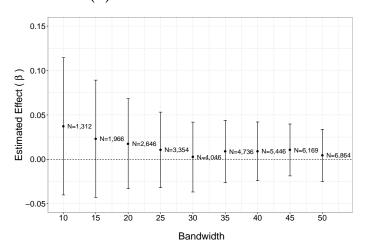

Note: The figure shows the distribution of the time distance to the podium (i.e., running variable). We plot an Epanechnikov kernel function with a bandwidth of 0.05 seconds. The dashed vertical lines illustrate our preferred bandwidth choice of 0.15 seconds.

Figure A.8: Regression Results using Different Bandwidths

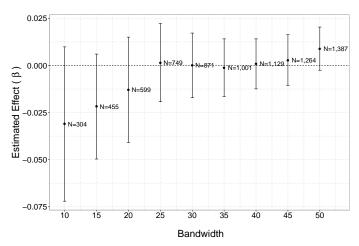

(a) Effect on Media Attention

(b) Effect on Performance

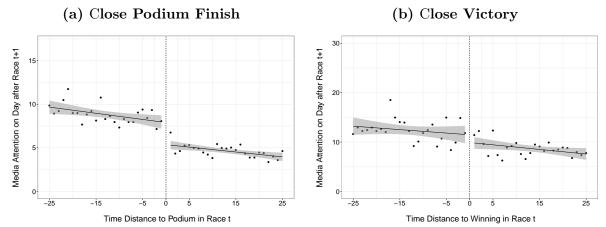

(c) Effect on Inverse Betting Odds

Note: The figure shows the results from estimating the effect of a podium finish on media attention on the day after the competition (Panel (a)), the probability to win the next race (Panel (b)), and average inverse betting odds in the next race (Panel (c)) using bandwidths from 10 to 50 hundredths of a second. The dots indicate the point estimate, while the bars depict the 95% confidence interval.

Figure A.9: Effect of Top Ranks on NewsLibrary Media Attention

Note: The figures show a linear fit for the number of media articles (using NewsLibrary data) that mention an athlete (on the day after a race took place) for both treatment (left) and control group (right). In panel (a) we compare victory and non-victory while in panel (b) athletes on the podium are compared with those missing it by 0.25 seconds or less. The grey region indicates the 95% confidence interval.

Appendix B: Attrition Bias

One problem that may arise when estimating the effect of a ranking position on future performance is that athletes differ with respect to their probability of survival, i.e. not crashing. If this probability is related to success our estimates for performance would be biased. It could be, for example, that athletes who are very successful once adopt a riskier behavior in subsequent races in order to be successful again.

Following Frangakis and Rubin (2002), we denote athletes with a constant low (high) probability of survival by DD (LL). While the survival probability of this set of athletes is unaffected by the treatment, other athletes adjust their behavior when being treated, in other words after a quasi-random top rank. The athletes in subset LD adopt a more risky strategy after treatment while those in subset DL follow a low-risk strategy in case they achieve a quasi-random top rank. In the regression of the probability of survival ($s_{i,j+1}$) on treatment $D_{i,j}$ and controls for a athlete's own characteristics $\mathbf{X}_{i,j}$ and competitors' characteristics $\mathbf{Z}_{i,j}$

$$s_{i,j+1} = D_{i,j}\tau + \mathbf{X}_{i,j}\gamma + \mathbf{Z}_{i,j}\delta + \varepsilon_{i,j}$$
(5)

we should expect $\tau=0$ for the two types with constant behavior (DD and LL). For types DL we expect $\tau<0$ and for types LD we should see an increase in the probability of survival. Thus we have two problems if the coefficient τ is significantly negative: First, our estimates with respect to subsequent performance would be biased upwards because we would only observe treated athletes in case they are successful in subsequent races. Second, the overall gain from imposing a ranking will be reduced and perhaps negative if top ranks lead to a strong increase in risky behavior.²⁸

²⁸This finding would be in line with research on addiction to success.

Appendix C: Relative Performance Measures and SUTVA

The Stable Unit Treatment Value Assumption (SUTVA) is fundamental to most estimators used in the program evaluation literature. It allows to write the treatment status of individual i only dependent on her assignment, and the outcome of individual i only dependent on her assignment and treatment status. More formally, SUTVA is defined as follows (according to Angrist, Imbens and Rubin (1996, p.446)):

(a) If
$$Z_i = Z'_i$$
, then $D(\mathbf{Z}) = D(\mathbf{Z}')$

(b) If
$$Z_i = Z'_i$$
, then $Y_i(\mathbf{D}, \mathbf{Z}) = Y_i(\mathbf{D}', \mathbf{Z}')$

This allows us to write $D_i(\mathbf{Z}) = D_i(Z_i)$ and $Y_i(\mathbf{D}, \mathbf{Z}) = Y_i(D_i, Z_i)$.

Applying this assumption to our paper, let us define the vector of final times \mathbf{T} in race j as well as vectors of assignments (to the podium) (\mathbf{Z}) and treatments (\mathbf{D}):

$$\mathbf{T} = \begin{pmatrix} t_1 \\ t_2 \\ t_3 \\ \vdots \\ t_N \end{pmatrix} \qquad \mathbf{Z} = \begin{pmatrix} z_1 \\ z_2 \\ z_3 \\ \vdots \\ z_N \end{pmatrix} \qquad \mathbf{D} = \begin{pmatrix} d_1 \\ d_2 \\ d_3 \\ \vdots \\ d_N \end{pmatrix}$$
(6)

We assume that there is a positive probability of a crash. We model survival as

$$S_i = \begin{cases} 1 \text{ if } S_i^* > 0\\ 0 \text{ if } S_i^* \le 0 \end{cases}$$
 (7)

with

$$S_i^* = \theta_i a_1 + \mu_i + \varepsilon_i \tag{8}$$

where S_i^* is a latent variable, θ_i is an athlete's skill, $a_1 > 0$ is a coefficient, μ_j is a race fixed effect, ε_i is an unobserved component. With $a_2 < 0$ being some coefficient, the final time can be written as

$$T_i = \begin{cases} \text{NA} & \text{if } S_i = 0\\ \theta_i a_2 + \delta_j + v_i & \text{if } S_i = 1 \end{cases}$$

$$\tag{9}$$

We consider a specific race with three top athletes under two circumstances. First, conditions are equal for all athletes. Second, the three top athletes $(i \in \{1, 2, 3\})$ suffer from bad weather conditions, which makes it impossible for them to attain a place on the podium.

$$\mathbf{Z} = \mathbf{D} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 1 \end{pmatrix} \qquad \mathbf{Z}' = \mathbf{D}' = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{10}$$

In this case, it is obvious that the assignment status of individuals 4–6 depends upon the assignment of the three top athletes. However, since $D_i = Z_i$, the individual treatment status D_i can still be written as a function of the assignment Z_i .

Turning to the implication (b) of SUTVA, we first note that our outcome can be written purely as a function of the assignment, i.e. $Y_i(\mathbf{Z}, \mathbf{D}) = Y_i(\mathbf{Z})$. This comes from the fuzzy design where $\mathbf{Z} = \mathbf{D}$.

Any measure of relative performance —such as the position— depends on a athlete's own time as well as the competitors' times: $P_{i,j} = g(T_{i,j}, T_{s,j}) = g(\theta_i, \lambda_{i,j}, n_{i,j}, \theta_s, \lambda_{s,j}, n_{s,j}) \quad \forall s \neq i$. The winner's time is often the benchmark and can be written as

$$T_{\text{win},j} = \min_{i \in S} (T_{i,j}) \tag{11}$$

where S indicates the set of survivors. For the sake of illustration, we specify equation (9) for survivors as

$$T_{i,j} = \theta_i a_2 + \delta_j + \text{Exp}_i a_3 + \text{Exp}_i^2 a_4 + \tau_i a_5 + u_i$$
 (12)

where Exp_i is experience and treatment τ_i equals one if athlete i won the last race and zero otherwise. Imagine that the winner in a given race j is determined by a tiny time difference between athlete 1 and 4. Assume both athletes to have the same skill level θ_i , but while athlete 1 is a rookie, athlete 4 is an experienced and successful athlete. Athlete i's relevant outcome $Y_i = P_{i,j+1}$ in the next race depends on the performance of the best athlete in that race. So if athlete 4 wins today and $a_5 \neq 0$, $T_{\min,j+1}$ is likely to be lower than if athlete 2 wins (because athlete 4 is more experienced and experience positively affects performance).

Therefore, the outcome of athlete i in race j+1 is likely to depend on the assignment of the winner (note that treatment and assignment are henceforth defined for the victory treatment and not the podium treatment as above)

$$\mathbf{Z} = \mathbf{D} = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \qquad \mathbf{Z}' = \mathbf{D}' = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix} \quad \text{and} \quad Y_i(\mathbf{Z}) \neq Y_i(\mathbf{Z}')$$

which violates definition (b) of SUTVA.

This problem arises to different extents with all kinds of relative performance measures. Thus we limit our analysis to using absolute race times as outcome variable for performance.

Appendix D: Sample Race

Table D.1: Sample Race for Illustrative Purpose

Rank	Name	Nationality	Time	Difference	Articles
1	Benjamin Raich	AUT	1:36.66		13
2	Akira Sasaki	JAP	1:36.83	0.17	9
3	Thomas Grandi	FRA	1:37.17	0.51	15
4	Michael Janyk	USA	1:37.19	0.53	4
5	Ted Ligety	USA	1:37.54	0.88	5

Table D.1 shows the result of the 2006/07 Men World Cup Slalom race in Shigakogen, Japan. We observe that Thomas Grandi achieved a podium finish because he was 0.02 seconds ahead of Michael Janyk. This race result can be used to illustrate how we define treatment and control group in our estimation. First, we take the time of the third-ranked athlete (1:37.17 in this case). Then we compute a 0.15 seconds window around this race time. All athletes within this time window (1:37.02 to 1:37.32) are part of our estimation sample. Every athlete in this group who finished on the podium is in the treatment group. Every other athlete in the estimation sample serves as part of the control group.

Appendix E: Two Examples of Media Attention

The following two clips from newspapers illustrate the kind of articles we find using Swissdox or NewsLibrary to measure media attention.

VONN TOPS RIVAL IN GS Author: From wire dispatches

Article Text

American **Lindsey Vonn** beat rival Tina Maze of Slovenia on Maze's home snow and in her best discipline Saturday, earning a surprising victory in a giant slalom in Maribor.

Maze had a chance to secure her third giant slalom discipline title with a victory and led after a near-perfect first run, but a poor start to the second cost her valuable time and she finished 0.08 seconds behind **Vonn**.

Vonn proved again that she is back to her best after an illness by putting down two good runs in what is traditionally her weakest event to win in 2:22.2.

Vonn was third after the first run but overcame several errors to have the fastest time in the second and create a margin that Maze couldn't bridge.

"In the second run I decided, OK, it's all or nothing, I had to go for it," **Vonn** said. "It's been a rough year for me in GS, so it's just perfect."

Vonn earned her first GS victory since March 2012, and her second win in a week after taking the downhill at Cortina D'Ampezzo.

With her 59th World Cup win overall, she's just three away from equaling Annemarie Moser Proell's record on the women's side.

Proeir's record on the women's side. More skiling on the World Cup downhill in More skiling Dominik Paris became the second Italian skier to win the classic men's World Cup downhill in 1:57.56 to follow in the footsteps of Kristian Ghedina, who won in 1998. World downhill champion Erin Guy of Canada trailed Paris by 0.13 in second place, and Hannes Reichelt of Austria came 0.36 back in third.

Hall of Fame jockey Russell Baze rode the 50,000th thoroughbred race of his career. Baze, 54, finished third in his historic race Friday at Golden Gate Fields near San Francisco, although he was allowed in the winner's circle afterward to pose for a photo. He swept the first three races on the eight-race card. Baze has notched 11,839 victories from his 50,000 mounts, and both totals are North American racing records, according to Equibase.

Tina Maze continue d'affoler les statistiques

Ski alpin2edu géant samedi derrière Lindsey Vonn , la Slovène domine le slalom sur sa piste de Marihor

Tina Maze n'est pas restée longtemps dans l'ombre à Maribor. Eclipsée samedi en géant par Lindsey Vonn , la Slovène a signé un succès éclatant lors du slalom dominical. Comme la veille, Tina Maze pointait en tête après la manche initiale. Mais la comparaison s'est arrêtée là. Battue d'un souffle (0"08) samedi par une Lindsey Vonn ressuscitée en géant, la Slovène n'a pas essuyé un deuxième camouflet sur ses terres. Meilleur temps sur les deux tracés, elle s'est offert un triomphe devant un public en délire, reléguant sa dauphine suédoise Frida Hansdotter (à 0"86) au rang de faire-valoir.

«En franchissant la ligne, je n'ai pas vu mon classement. Mais quand j'ai entendu la clameur de la foule, j'ai su que c'était bon», a raconté la superstar nationale.

Avec cette nouvelle victoire, Tina Maze n'en finit plus d'affoler les statistiques. En 25 courses cet hiver, elle est montée à 17 reprises sur le podium, dont sept fois sur la plus haute marche. Sauf accident, elle va exploser le mythique record de Hermann Maier, qui avait accumulé 2000 points en 1999-2000. La Slovène en est actuellement à 1654 unités, alors qu'il reste douze épreuves.

La fille aux skis suisses (Stöckli) s'apprête aussi à faire une razzia parmi les globes. Celui du géant est mathématiquement assuré et celui du classement général devrait l'être bientôt. Hier, elle s'est aussi replacée en slalom à seulement 13 points de Mikaela Shiffrin. Le prodige américain, qui restait sur deux succès, a payé cher une grosse faute en première manche et a dû se contenter de la 8e place.

Côté suisse, Wendy Holdener a continué de jouer les métronomes. Toujours classée entre le 9e et le 17e rang cet hiver en slalom, la Schwytzoise a terminé 10e à Maribor. Une régularité remarquable pour une skieuse de 19 ans. Il ne lui manque plus qu'une place aux avant-postes pour franchir un nouveau palier dans sa prometteuse carrière. Il a ensuite fallu remonter au 21e rang pour retrouver Michelle Gisin. Un classement qui reste bon à prendre pour la «rookie» obwaldienne, qui dispute à 19 ans sa première saison en Coupe du monde. La déception suisse du week-end est venue de Lara Gut, éliminée samedi en géant. Brillante en début de saison dans la discipline avec des 4es places à Aspen et à Saint-Moritz, la Tessinoise n'y arrive plus avec un 17e rang comme meilleur classement lors de ses quatre dernières sorties. SI

Note: The figures show two examples of media attention found in NewsLibrary (left-hand side) as well as Swissdox (right-hand side) for Linsey Vonn and Tina Maze in the aftermath of World Cup races in late January of 2013.
